Abstract

This work is intended to be the second publication in a series of papers reporting on the spectro-photometric properties of cometary analogues measured in the laboratory. Herein, we provide *in-situ* hyperspectral imaging data in the 0.40 – 2.35 μm range from three sublimation experiments under simulated space conditions in thermal vacuum from samples made of water ice, carbonaceous compounds and complex organic molecules. The dataset is complemented by measurements of the bidirectional reflectance in the visible (750 nm) spectral range before and after sublimation. A qualitative characterization of surface evolution processes is provided as well as a description of morphological changes during the simulation experiment.

The aim of these experiments is to mimic the spectrum of comet 67P/Churyumov-Gerasimenko (67P) as acquired by the Rosetta mission by applying sublimation experiments on the mixtures of water ice with a complex organic mate-

rial (tholins) and carbonaceous compounds (carbon black; activated charcoal) studied in our companion publication (Jost et al., submitted). Sublimation experiments are needed to develop the particular texture (high porosity), expected on the nucleus' surface, which might have a strong influence on spectrophotometric properties. The spectrally best matching mixtures of non volatile organic molecules from Jost et al. (submitted) are mixed with fine grained water ice particles and evolved in a thermal vacuum chamber, in order to monitor the influence of the sublimation process on their spectro-photometric properties.

We demonstrate that the way the water ice and the non-volatile constituents are mixed, plays a major role in the formation and evolution of a surface residue mantle as well as having influence on the consolidation processes of the underlying ice. Additionally it results in different activity patterns under simulated insolation cycles. Further we show that the phase curves of samples having a porous surface mantle layer display higher coincidence with data of 67P than the phase curves of the samples having a more compact surface layer with smooth texture.

The analysis of spectral absorption bands of water ice in the near-infrared (NIR) range, similar to those acquired by the VIRTIS instrument onboard Rosetta, allows to link compositional considerations with surface activity and texture.

Keywords: Hyperspectral imaging, water ice, organics, comets

1. Introduction

Cometary surfaces are in permanent change through sublimation processes. The evolution of ices mixed with minerals and organic components is complex and requires laboratory constraint. Until today only a few laboratory studies
5 have been performed to investigate the sublimation of ices mixed with minerals and organic components, prepared as analogues of cometary nuclei. In the

1970's simulation experiments were made at the Joffe Institute in Leningrad (Dobrovolsky and Kaimakov, 1977), mixing ice with minerals and/or organics. Later in 1980's a group at JPL in Pasadena carried out sublimation experiments of water ice samples prepared from suspensions with phyllosilicates, other silicates and organic matter (Saunders et al., 1986; Storrs et al., 1988). The most extensive and comprehensive campaign was the KOSI (KOMeten-SIMulations) experiments performed at the DLR space simulator in Köln from 1987 to 1993 (e.g. Gruen et al., 1991; Gruen et al., 1993; Seiferlin et al., 1995). The focus of these experiments laid, similar to our own experiments, on the surface evolution and sublimation processes under simulated space conditions, but with larger scale samples. Although 11 experimental runs were performed, there was no systematic approach in mixing constituents. For the KOSI 3, 4 and 6 experiments, Oehler and Neukum (1991) measured the reflectance spectra between 0.36 and 2.5 μm before and after the sublimation experiments under three different illumination angles.

The benefit of our recent experiments in Bern (Pommerol et al., 2015a; Poch et al., 2016a,b) is the possibility to acquire spectral data *in-situ* during the sublimation process through a window of the vacuum chamber. In this work a photometric characterization before and after the sublimation is added to investigate the bidirectional reflectance quantities.

In our companion paper (Jost et al., submitted) we performed a systematic laboratory study of potential cometary compositions in order to match the observed surface properties of 67P. We measured the bidirectional reflectance of carbon-tholin-, carbon-water ice- and tholin-water ice-mixtures. It was possible to reproduce the individual spectrophotometric parameters (albedo, spectrum, phase reddening, phase curve) of 67P, however no mixture was able to fit all parameters altogether.

We have indicated that the samples with the highest porosities best match

the phase curve of 67P. Spectral considerations show that the particle size of the darkening agent has a lower limit of a few hundred nanometres to several
40 micrometres and cannot be dominated by particles in the range of some tens of nanometres. This finding is based on the blue spectral slope observed on nanometre-sized carbon black and the arch-shaped spectral curve when mixing carbon black with tholins.

45 Further our findings from Jost et al. (submitted) support the idea that the bright ice patches observed by OSIRIS and VIRTIS should be relatively dust free at small scale as already small dust contaminations are able to decrease the albedo dramatically.

50 In this study we have selected the mixtures with closest spectral fit to 67P from the companion work and added fine grained water ice particles to investigate sublimation processes. The integrated VIS-NIR reflectance spectra of both carbon types (carbon black, activated charcoal) as well their mixtures with tholins from Jost et al. (submitted) are shown in Fig. 1. These two mixtures
55 are the basis for the current work where a series of three individual sublimation experiments was performed using the same production protocol, but different compositions. Mixtures of fine grained spherical ice particles with carbonaceous compounds and complex organic matter were sublimed and spectroscopically investigated. We report on the acquired spectra in the $0.40 - 2.35 \mu\text{m}$ range,
60 resulting in a disappearance of water absorption bands as the ice sublimates and a residue layer accumulates. Further we characterise the spectral slopes and the visible reflectance during the sublimation process.

2. Methods

2.1. SCITEAS

65 All sublimation experiments were performed with the SCITEAS setup (Simulation Chamber for Imaging the Temporal Evolution of Analogue Samples). In this

Figure 1: Integrated reflectance spectra of the non-volatile components as used for sublimation experiments in this work. The selection is based on the findings of [Jost et al. \(submitted\)](#).

paragraph only a short description is provided, more detailed information of this simulation chamber and its imaging system can be found in [Pommerol et al. \(2015a\)](#).

70

The SCITEAS thermal-vacuum chamber accommodates a cylindrical sample holder of 160 mm diameter that can be equipped with up to 4 small sample containers. A hyperspectral imaging system characterizes the reflected light from the sample in the 0.40 to 2.50 μm spectral range through a 15 mm-thick fused quartz window. The sample is illuminated from a monochromatic light source (halogen lamp coupled to a monochromator) through the window by an optical fibre. Two broadband cameras, VIS and NIR, placed at 200 and 300 mm above the window collect the scattered light at an angle of about 13° with respect of nadir direction. The visible camera covers a spectral range of 0.38 – 1.08 μm , the near-infrared camera 0.85 – 2.50 μm . To create hyperspectral cubes the monochromatic light source shifts the wavelength through the spectral range (with a sampling of 6 – 20 nm). At each wavelength an image is acquired.

The sample holder is radiatively cooled from a cylindrical shroud with continuous liquid nitrogen circulation. The chamber is evacuated using two membrane primary pumps and one turbomolecular pump. The long term sample holder

85

temperatures achieved with this cooling system lie in the -90 to -75 °C range, depending on the vertical distance from the window. The minimum pressure lies between 10^{-5} mbar and 10^{-6} mbar, depending on the content of volatiles.

90

A solar simulator (L.O.T. Quantum Design, product # LS0308) with a 300 W Xe arc lamp yielding an intensity of 1 solar constant on a 40 mm diameter spot is placed above the window of the vacuum chamber to illuminate the samples.

95

During all three experiments the NIR data quality was strongly influenced by temperature fluctuations in the laboratory. The cycling operation mode of the ventilation and cooling system lead to variations of dark current of the sensor. This effect could be directly observed in the spectra as temporal fluctuations in reflectance, as the spectra are acquired as a time sequence, scanning the spectral range. We were able to compensate for this problem to some extent by analysing the signal within a non-illuminated area beside the sample holder, and correcting the dark level in the calibration. But some wave-like artefacts can still be seen on the spectra. Due to a very low albedo of our sample materials in these experiments, the signal to noise ratio was critically low during the first two experiments, especially in the NIR range. By optimising the exposure times and performing multiple acquisitions at each wavelength, which are averaged, it was possible to reduce spectral noise.

100

105

2.2. PHIRE-2

110

115

The bidirectional reflectance measurements presented in this work were acquired using the PHIRE-2 radio-goniometer. Details about the instrument and its calibration can be found in [Pommerol et al. \(2011\)](#) and [Jost et al. \(2016\)](#), therefore only basic specifications are summarized here. The goniometer is located inside a freezer, operated at -35 °C for ice-bearing samples. Non-ice samples were measured at room temperature. A collimated light source is equipped with six bandpass filters (450/550/650/750/905/1064 nm) and illuminates the

samples under an incidence angle of 0° to 60° . The scattered light is measured with a silicon photovoltaic sensor on another mobile arm, the -80° to $+80^\circ$ emission angle range. The phase angle α is the angle between incidence and emission direction. In this work only the 750 nm-filter was used in order to reduce the acquisition time to a minimum and prevent sublimation effects.

PHIRE-2 can be equipped with either a mirror head or a beam splitting system (Jost et al., 2016). The advantage of the beamsplitter is the possibility of measuring very low phase angles (down to 0°) compared to a mirror, which blocks the incoming light at phase angles smaller than 4° . However the signal is by a factor 4 lower with the beamsplitter than with the mirror. This plays no role for bright samples as studied in Jost et al. (2016), but is a serious issue in case of very dark samples as in this study.

2.3. Sample material

The sample compositions were selected in order to act as cometary analogues after significant sublimation. The basic constituent is fine grained ice produced by spraying water into liquid nitrogen. As composition of non-volatiles a combination of complex organic material and carbonaceous compounds was used. The mixtures were selected along the results from Jost et al. (2016), having highest coincidence in spectrum and albedo with comet 67P (Fornasier et al., 2015). The amount of non-volatiles in our experiments (0.3 – 2.0 %) are by one to two orders of magnitude lower than in a comet’s nucleus, but as we sublime the ice in the uppermost layers, the (photometrically relevant) ratio may be comparable. To see effects of different spatial distributions of non-volatiles inside the ice matrix, two different mixing types were adopted.

All characteristics concerning sample composition and measurement configurations are listed up in Table 1. Experiment #1 was performed using carbon black as dark compound, experiments #2 and #3 were prepared using activated charcoal. The mixing ratio of charcoal and tholins was defined by the closest

match of this mixture compared to the visible spectrum of 67P (Jost et al., submitted). Experiment #3 has a higher initial concentration of non-volatiles compared to #2 (2 % instead of 0.3 %). The sublimation duration was chosen to have a relatively ice free residue layer with low surface irregularities.

Table 1: Characteristics of sublimation experiments.

	Experiment #1	Experiment #2	Experiment #3
Initial water ice content	99.7 wt % ($67 \pm 31 \mu\text{m}$)	99.7 wt % ($67 \pm 31 \mu\text{m}$)	98.0 wt % ($67 \pm 31 \mu\text{m}$)
Initial carbonaceous compound content	0.2 wt % carbon black (42 nm)	0.27 wt % activated charcoal ($17.6 \pm 11.3 \mu\text{m}$)	1.8 wt % activated charcoal ($17.6 \pm 11.3 \mu\text{m}$)
Initial organics content	0.1 wt % titan tholins ($315 \pm 185 \text{ nm}$)	0.03 wt % titan tholins ($315 \pm 185 \text{ nm}$)	0.2 wt % titan tholins ($315 \pm 185 \text{ nm}$)
Sample types	intra + inter-mixture	intra + inter-mixture pure charcoal/tholins powder	intra + inter-mixture coarse fraction ($> 800 \mu\text{m}$) of intra-mixture from sieving pure ice
Bulk density	$0.4 - 0.5 \text{ g/cm}^3$	$0.4 - 0.5 \text{ g/cm}^3$	$0.4 - 0.5 \text{ g/cm}^3$
Sublimation duration before 2nd goniometer measurement	6.45 h	14.25 h	6.20 h
Continuation after 2nd goniometer measurement	no	no	7.5 h normal sublimation afterwards day-night cycles with solar simulator

2.3.1. Ice particles

The spherical water ice particles used in this study have a diameter of $67 \mu\text{m}$ with a standard deviation of $31 \mu\text{m}$. For production details see Yoldi et al. (2015).

2.3.2. Tholins

We used tholins as analogues of the complex organic matter, because they exhibit a strong red spectral slope from 0.2 to $1.0 \mu\text{m}$, allowing us to vary the redness and albedo of our samples by mixing it with darker and spectrally different carbonaceous compounds. The word “tholins” was first used by Sagan and Khare (1979) to describe the complex macromolecular organics formed after the irradiation of a gas mixture composed of simple molecules, displaying a orange-brownish colour. The yellowish to dark organic residues obtained after the irradiation of simple ices have also been named tholins or “ice tholins” (see e.g. McDonald et al., 1996). The tholins used in this work were previously utilised by Poch et al. (2016a) and Poch et al. (2016b). The

material was produced in a plasma of 95 % N₂ and 5 % CH₄, using the PAM-PRE setup (Sciamma-O'Brien et al., 2010; Szopa et al., 2006). Tholins are made of a complex mixture of molecular and macromolecular material composed of aliphatic hydrocarbons, nitriles, imines, amines or N-bearing aromatic compounds (Bernard et al., 2006; Carrasco et al., 2009; Pernot et al., 2010; Quirico et al., 2008; Gautier et al., 2014; Gautier et al., 2016). The complex organic molecules are arranged in high porosity spherical grains with a mean diameter of 315 ± 185 nm (Carrasco et al., 2009). Their optical indices have been characterised by Mahjoub et al. (2012) and the reflectance spectra by de Bergh et al. (2008).

2.3.3. Carbon powders

We used carbon powders as analogues of the darkening agent(s) of cometary surfaces. Amorphous carbon inherited from interstellar dust could represent up to 10 % of cometary materials (Wooden, 2008) and could partly contribute to the low albedo of cometary nuclei. However such a high amount of pure carbon in cometary refractory material is questionable, since by date only complex organic materials rather than pure carbons have been found in natural extraterrestrial samples like porous interplanetary dust particles (IDP) or STARDUST samples (e.g. Sandford et al., 2006; Brownlee, 2014).

185 Carbon black

The carbon black used in this work was purchased from Alfa-Aesar (product 3972). It is the solid residue obtained by acetylene combustion and consists of amorphous carbon shaped in spherical particles with an average diameter of 42 nm. The structure of the individual particles cannot be resolved in Fig. 2a.

190 Activated charcoal

The activated charcoal used in this study was purchased from Sigma-Aldrich (Product C3345). This granular carbon has been prepared from wood particles which have been impregnated with a chemical agent and pyrolysed to produce very porous particles of pure carbon. The particles are smaller than 75 μ m

195 according to the manufacturer. Our own microscope image analysis resulted in an average diameter of $17.6\text{ }\mu\text{m}$ with a standard deviation of $11.3\text{ }\mu\text{m}$. The particle shape is irregular with sharp edges (see Fig. 2b). There is very little formation of agglomerates.

Figure 2: Environmental scanning electron microscope images of carbon black (a) and activated charcoal (b) acquired at Institute of Geography at University of Bern.

2.3.4. *Mixing types*

200 We developed two different mixing procedures for producing two types of laboratory analogues:

1. Intra-mixture, tholins and carbon particles are suspended in water prior to the freezing process. The non-volatiles are present as inclusions within the icy grains. The suspension is prepared by ultrasonication, performed with a Hielscher 200Ht ultrasonic unit equipped with a 7 mm diameter sonotrode. The duration of ultrasonication was limited to about 1 min to keep the suspension temperature below $30\text{ }^{\circ}\text{C}$, to avoid thermal changes.
  2. Inter-mixture, non-volatiles are mixed intimately with the pure water ice particles at the grain level. The mixture was prepared in an aluminium bottle cooled to nitrogen temperature, by adding freshly produced ice and pre-cooled non-volatiles. The bottle was then agitated using a Vortex-Genie2 mixer at full speed for about 1 min, interrupted by re-cooling the bottle in liquid nitrogen.
- 210

2.3.5. Sample preparation

215 The samples are deposited in aluminium compartments of dimensions of
20x40x20 mm. The deposition of sample material into the sample holder was
done by sieving (800 μm mesh size) to avoid big agglomerates and to produce
homogeneous samples of controlled bulk density. There is no compression, the
piled material is cut with a spatula and a thin layer of material is sieved on
220 top to obtain a random surface orientation. In experiment #3 the remaining
material from the sieving process was used as a separate sample (coarse-grained
intra-mixture) with a very granular structure.

2.3.6. Measurement sequence

After sample production and preparation in the compartments the intra-
225 and inter-mixtures samples were measured in the PHIRE-2 goniometer individ-
ually, taking 40 min each. The other sample was stored under a cover in a chest
freezer at -40°C . After the goniometer data acquisition the compartments
were arranged in a bigger sample holder, pre-cooled to liquid nitrogen temper-
ature, fitting into the vacuum chamber.

230 After the sample holder was placed into the SCITEAS chamber and the
chamber was closed, the liquid nitrogen cooling cycle was started. After some
minutes the primary and the secondary vacuum pumps were started stepwise,
reaching a final pressure of 10^{-5} mbar after ~ 30 min. When the cooling stabi-
235 lized ~ 1 h after the beginning, the ambient light in the laboratory was turned
off in order to acquire a first hyperspectral cube.

The aim of these sublimation experiments was to create a compact, flat
residue layer of non-volatiles on the samples. However we wanted to avoid ejection
240 of these layers (as observed in previous experiments), to keep a smooth
texture in order to be able to acquire a second BRDF dataset with the goniome-
ter after some hours.

Experiments #1 and #3 had sublimation durations of 6.45 h, and 6.20 h
245 respectively. The sample from the experiment #2 were sublimed for 14.25 h
due to a higher initial brightness.

The samples from the experiment #3 were re-inserted into SCITEAS after
the second measurement in PHIRE-2 and left to sublime during additional 7.5 h.
250 Afterwards a sequence of 3 illumination cycles with the solar simulator was run
(20 min illumination, 20 min dark). Due to the 40 mm diameter illumination
field, all samples are only illuminated partially, some areas stay always in the
shadow (see Fig. 7).

255 All sublimation occurring without illumination is driven by thermal IR flux
coming from the window of the vacuum chamber. The calculated IR flux is
 $\sim 5 \text{ mW/cm}^2$ considering the window temperatures and the vertical distance of
the samples from the window. The energy input from the fluorescent lamps in
the laboratory is negligible.

260 3. Results

3.1. Spectrophotometry and surface morphology

3.1.1. Experiment #1: 99.7% water ice + 0.2% carbon black + 0.1% tholins

For experiment #1 ice grains were prepared as inter- and intra-mixtures
using a powder of non-volatile materials made of 33 % tholins and 67 % car-
265 bon black and sublimated during 6.45 h. The integrated reflectance spectrum
(hemispherical albedo) of the dry powder acquired with PHIRE-2 can be found
in Fig. 1. It shows a steep red slope from 450 to 650 nm and a shallow blue
slope towards the NIR.

270 The freshly deposited inter-mixture sample (Fig. 3a) has a greyish tone, the
intra-mixture is slightly darker and less yellowish. The middle of the sample
is covered with frost streak deposited from air flow above the surface at the

beginning of the experiment prior to the start of the vacuum pumps. After 15 min the frost layer is sublimated and the inter-mixture displays a yellowish tone (Fig. 3b). The intra-mixture is still darker with coverage of black ice grains on the surface. Two hours after the start the intra-mixture formed an uniform, black residue layer (Fig. 3c), while the inter-mixture is not as yellowish as before and has some transparent ice grains on the surface. It took about 4 h until the inter-mixture had a visually similar smooth residue layer as the intra-mixture, with a slight yellowish tone and no ice visible.

The reflectance spectrum in the $0.40 - 2.35 \mu\text{m}$ range acquired with the SCITEAS hyperspectral imaging system can be found in Fig. 4. Fig. 4a compares the spectra of the two mixture types after 1 h of sublimation. The intra-mixture is about 50 – 70 % darker and more linear red compared to a concave shape of the inter-mixture below $1 \mu\text{m}$. The spectra are featureless in the visible. Data up to $0.94 \mu\text{m}$ is acquired with the visible camera and less noisy due the higher signal. The NIR spectra clearly show the two water ice absorption bands at $1.5 \mu\text{m}$ and $2.0 \mu\text{m}$; the bands of the inter-mixture are a bit more pronounced and the spectra less noisy.

The temporal evolution of the reflectance spectrum of the inter-mixture sample is shown in Fig. 4b, the reflectance in the visible drops by almost 100 % after 3.10 h compared to the measurement after 1 h and the water absorption bands start to disappear. At the band center of the $2.0 \mu\text{m}$ band the reflectance increases by a factor of 2 between the first and the last spectrum.

3.1.2. Experiment #2: 99.7% water ice + 0.27% charcoal + 0.03% tholins

In experiment #2 a mixture of 10 % tholins and 90 % activated charcoal was used to mix with ice. The PHIRE-2 integrated spectrum of this powder can be found in Fig. 1, it is monotonically red with a steeper slope in 450 to 650 nm range originating from the tholins. Compared to experiment #1 where nanometre-sized carbon black was used as darkening agent, experiment #2 con-

Figure 3: Time sequences of sublimation experiments #1 (a-c) and #2 (d-f). The intra-mixture sample is always positioned on the right side, the inter-mixture on the left. The green boxes indicate the regions of interest (ROI) for spectral analysis. The streaks in a) originate from frost deposit at the beginning of the experiment and have sublimed in b). The intra-mixture in b) shows some dark grains in the top layer while the inter-mixture appears still uniform. After 2 h (c) the inter-mixture shows transparent ice grains on the surface while the intra-mixture has an uniform residue layer of dark material. Experiment #2 displays a significant yellowish colour originating from tholins. Overall the sample is brighter than experiment #1 due to bigger carbon particles, besides the identical mixing ratios. Again the intra-mixture has a more heterogeneous colour, with some dark grains on the surface. After 14 h (f) the inter mixture shows an almost uniform texture, the intra-mixture experienced some gas driven ejection events, creating a filamentous matrix with a heterogeneous texture with exposed ice.

Figure 4: Reflectance spectra from experiment #1 in the $0.4 - 2.35 \mu\text{m}$ range. a) comparison of the mixture types after 1 h of sublimation. The intra-mixture is about 50 – 70 % darker in the visible spectral range and up to about $1.4 \mu\text{m}$, the reflectance in the water absorption bands at $1.5 \mu\text{m}$ and $2.0 \mu\text{m}$ is almost identical. b) temporal evolution of spectra from the inter-mixture. The sample becomes darker by nearly 100 % after 3.10 h. The water absorption bands start to vanish but are still present. At $2.0 \mu\text{m}$ the sample increases in reflectance after 4.20 h by nearly 100 % compared to the first spectrum.

tains micrometre-sized activated charcoal with an intrinsic red spectrum . Using a similar mass percentage of activated charcoal as of carbon black in the ice mixture increases the albedo, as the surface-to-mass ratio and therefore the total
 305 absorbing surface of bigger grains is lower. Thus samples of experiment #2 are significantly brighter than the ones of experiment #1 (Fig. 3).

The freshly deposited samples of experiment #2 are marginally covered by
 310 frost (Fig. 3d), the intra-mixture appears greyish, the inter-mixture yellowish. After 2.20 h (Fig. 3e) the surface of the inter-mixture look still homogeneous whereas the intra-mixture starts to display heterogeneities with some darker grains on the top layer. On the last step in the time sequence after 14 h, both samples have lost about 3 – 4 mm of material by sublimation (Fig. 3f). The
 315 inter-mixture has a yellowish-greyish colour with a smooth texture not showing any sign of ejection activity. The colour of the intra-mixture is dark-grey. The surface residue, forming a filamentous matrix with a heterogeneous texture is created by ejection events. These events are triggered by the upstreaming gas

which breaks and ejects parts of the residue layer. The bright underlying material, still containing large amounts of ice, gets exposed to the surface.

Figure 5: a) Reflectance spectra from experiment #2 after 1 and 2.45 h. Both samples become darker by about 50 – 80 % in the visible range, in the infrared the spectrum remains almost constant except at around 1.8 μm. The red slope in the visible is more linear for the intra-mixture, the spectrum of the inter-mixture has a concave shape. The same phenomenon is visible in experiment #1 (Fig. 4). b) Temporal evolution of the reflectance spectrum of the intra-mixture sample. There is no change in shape of the spectra in the visible range with time. The sample becomes darker with time in the visible, in the NIR the reflectance increases inside the water bands (1.5/2.0 μm) and decreases on the inter-bands (1.8/2.2 μm).

Reflectance spectra of experiment #2 are plotted in Fig. 5. In Fig. 5a spectra of both mixing-types are compared at two times. Again the intra-mixture is generally darker and has a more linear spectrum in the visible range than the inter-mixture which is concave shaped. The NIR spectrum of the mixing-types are nearly identical. After 1.45 h of sublimation both samples decrease in reflectance in the visible by 50 – 80 % but the shapes of the spectra remain the same. In the NIR the reflectance at the centres of the water ice bands stays almost the same, but is decreased at the local reflectance maximum at 1.8 μm. An extended time sequence (Fig. 5b) of the mixture up to 13.15 h displays a steady decrease in reflectance in the VIS with a constant slope angle and vanishing water absorption bands in the NIR, but the bands remain always visible.

3.1.3. Experiment #3: 98% water ice + 1.8% charcoal + 0.2% tholins

335 Experiment #3 was prepared with the constituents as #2 but with a higher amount of contaminants versus water ice (2 % instead of 0.3 %) which makes the samples darker. A time sequence showing the evolution of the samples is provided in Fig. 6. In addition to two mixing-types (inter/intra) a sample of pure ice and a sample with the remains from the sieving process of the
340 intra-mixture are added. The remaining material from the sieving is made of agglomerates larger than 800 μm and appears much darker than the fine fraction obtained after the sieving process. Compared to experiments #1 and #2 the inter-mixture does not appear as yellowish. After 1 h (Fig. 6a) of sublimation the intra-mixture looks marginally darker with some dark grains on the surface,
345 but the colour of the inter- and intra-mixture appears very similar. Fig. 6b shows the samples after re-insertion into the vacuum chamber after the second measurement with the goniometer. The samples have been kept under a cover in a freezer at $-45\text{ }^{\circ}\text{C}$ for to 2 h. During the measurements the intra- and inter-mixtures spend 1 h inside the goniometer freezer each at $-35\text{ }^{\circ}\text{C}$ and exposed
350 to airflow. The samples lost their reddish colour and appear more greyish due to a thin frost layer.

Fig. 6c shows the samples after the first 20 min illumination cycle with the solar simulator at 1 solar constant. The position of the light spot can be seen
355 in Fig. 7. Already after 2 min of illumination a cm-sized patch of the intra-mixture was ejected and the underlying material was exposed. The ejecta of the inter-mixture are mm-sized and started only after 8 min. The later beginning indicates either a higher gas permeability or lower sublimation rate, the smaller patches a lower cohesion force. This is consistent with findings made
360 by Poch et al. (2016a,b). The coarse grained material shows no texture changes and ejection patches, only individual grains are redistributed across the surface. The pure ice shows no textural changes except that a buried temperature sensor is exposed and some ejected particles from the other samples are deposited.

Figure 6: Time sequences of sublimation experiment #3. The ROI used for spectral analysis are indicated in green, the ones of the illuminated area in blue. b) shows the samples after the measurement with the goniometer, where the vacuum chamber had to be opened, the samples removed and inserted again. This explains the re-deposition of frost that hides the reddish colour. c) shows the samples after 20 min of illumination with a 1 solar constant solar simulator in the central part (see Fig. 7). Inside the illuminated area of the intra- and inter-mixture the residue layers are ejected and fresh sample material is exposed. The $\sim 1.5 \text{ cm}^2$ residue patch of the intra-mixture was ejected after 2 min of illumination in one piece. The small patches of the inter-mixture lifted-off continuously after 8 min duration. After several cycles of illumination the exposed bright patches are re-surfaced and visually indistinguishable from the non-illuminated areas. The coarse fraction of the intra-mixture formed no solid residue layer, only individual grains are ejected and re-distributed, the granular texture stays visible until the end of the experiment. The pure ice displays no significant change in texture or ejection of grains. The temperature sensor gets exposed with time by mass loss and some dark grains from the other samples are deposited onto the surface.

Compared to the dark mixtures the pure ice has a higher sublimation rate. During 14.30 h the pure ice sample lost about 4 mm of material compared to ~ 2 mm on dark samples.

Fig. 6d shows the samples at the very end of the experiment after several illumination cycles. All samples appear a bit brighter than 3.30 h before, this is very likely an exposure/illumination effect as the copper wire and the anodized aluminium are also brighter. The mass loss of the pure ice sample is now ~ 6 mm, the intra- and inter-mixtures lost about 3 mm with a clear gradient towards the illuminated areas where more energy has been deposited. The pure ice shows no gradient as it is almost transparent in the spectral range of the solar simulator.

All patches on which ejection events occurred, have been re-surfaced by a dry mantle and are indistinguishable by eye in terms of colour from the non-illuminated areas. Due to the ejection events the texture became more rough in the illuminated areas. The coarse grained sample shows no textural changes throughout the entire experiment.

In Fig. 8a the first spectra after 1.10 h of the three dark samples are compared. The inter-mixture is ~ 20 % brighter than the intra-mixture in the VIS, both having a similar spectral shapes. The coarse grained intra-mixture is darker by a factor of 3. In the NIR range the intra- and inter-mixture display a comparable water absorption band depth, while the spectrum of the coarse grained sample shows less deep water ice absorption bands. After 17.35 h of sublimation (Fig. 8b) all samples show a monotonically red spectrum which is almost identical in the VIS and slight variations in the NIR where signal noise is higher. There is no signal of water ice left anymore. These three spectra are all from non-illuminated areas of the samples.

Figure 7: Experiment #3 during the 2nd illumination cycle. It is obvious that the residue layer is only ejected inside the illuminated areas, the shape of the intra-mixture patch follows exactly the spot geometry. The intra-mixture (lower left sample) residue layer is more cohesive than the one from the inter-mixture. The coarse fraction of intra-mixture shows no structural dichotomy between the illuminated and shadowed areas.

Figure 8: Reflectance spectra of all charcoal/tholin-bearing samples from experiment #3. a) first spectra after 1.10 h, the coarse fraction of intra-mixture is considerably darker throughout the entire spectral range, with less signature of water. The inter-mixture is about 20 % brighter than the intra-mixture in the visible and the local maxima at 1.8/2.2 μm) show lower reflectance values. b) Spectra of the non-illuminated areas from all samples at the end of the experiment. All samples display an almost identical spectrum without any hints of water ice in the NIR. The spectra are monotonically red with some instrumental artefacts clearly visible.

Fig. 9 shows spectra of the pure ice sample from experiment #3, measured
 395 at three different times. The analysed area on the sample was selected so that
 the outstanding temperature sensor was not incorporated. The spectra show
 only a minor darkening in the VIS range within the first 4 h where no ejecta
 from other samples was deposited. After 17.35 h the spectrum became darker
 by $\sim 25\%$ at 0.5 μm with a red slope towards 1.0 μm . In the NIR spectral
 400 range the three spectra are indistinguishable to the level of instrumental errors.
 Four water ice absorption bands at 1.05/1.25/1.51/2.02 μm are clearly visible.

The fact that the NIR spectrum remains unchanged with a handful of very
 small grains inside the analysed area on the sample, but the VIS spectrum be-
 405 comes darker and redder, leads to the conclusion that very fine grained tholin
 particles must have been deposited onto the surface of pure ice, invisible by
 eye. The fact that tholins have a very high albedo in the NIR would explain
 the unchanged spectrum in this region. This tholin powder could have been
 separated from the much bigger charcoal grains during the ejection events, or

410 have been lifted off separately by gas flow from deeper layers of the samples.

Figure 9: Spectra of the pure-ice sample from experiment #3. In the visible range the spectrum after 17.35 h is darker and redder due to the deposition of ejected charcoal/tholin-particles from the other samples. In the NIR the spectrum shows no changes with time, there is no obvious effect of particle size changes (see Fig. 1.2 in [Clark et al., 2013](#)) due to sintering effects. The calculation of band depths at 1.5/2.0 μm is illustrated. The two water ice absorption bands at 1.05/1.25 μm are clearly recognizable on the pure ice spectrum but are too weak to be distinguished on dark samples with lower signal-noise ratios. For definition of absorption bands see Tab. 11.1 in [Mastrapa et al., 2013](#).

The spectra of illuminated and non-illuminated areas across the surface of the inter-mixture at the end of experiment #3 are compared in [Fig. 10a](#). The illuminated area which was re-surfaced and has a rougher texture (see [Fig. 6d](#)) is $\sim 20\%$ brighter in the VIS up to 1.4 μm . The non-illuminated area shows a monotonically red spectrum in the NIR while the re-surfaced area shows features of the two most prominent water absorption bands at 1.5 and 2.0 μm . This becomes more pronounced when plotting the ratio of the two spectra: the non-illuminated spectrum is divided by the illuminated one ([Fig. 10b](#)). The deepening of bands at 1.5 and 2.0 μm and enhancement of inter-bands at 1.8 and 2.2 μm are clearly visible.

Figure 10: a) Spectral comparison of the illuminated (and re-surfaced) and the non-illuminated area. The re-surfaced area is $\sim 20\%$ brighter in the visible with a similar red slope and shows signatures of water ice. b) spectral ratio between the two areas: values >1 mean that the illuminated area is brighter, values <1 mean darker than the non-illuminated area. The water ice absorption bands become clearly recognizable in the NIR, indicating a water ice content in the re-surfaced area.

3.2. Bidirectional reflectance

The principal goal of these sublimation experiments was to acquire and compare BRDF before and after the sublimation process. In order to analyse only the photometric changes of the surface mantle and not being influenced by ejection events, the sublimation duration had to be kept short to avoid ejection events to occur on the mantle, but long enough to create a porous layer. This was achieved on all samples except the intra-mixture from experiment #2 (Fig. 3f). The BRDF-data from experiment #1 was already analysed and compared to 67P in Feller et al. (2016).

The phase curved acquired at 0° incidence angle and the 750 nm filter are plotted in Fig. 11, a) and c) show the two mixture types in absolute REFF, subfigures b) and d) show the same phase curves but normalized at 5° phase angle, to better see the curvatures. In all subfigures the phase curve of comet 67P/Churyumov-Gerasimenko, derived from Hapke parameters at 743 nm from Fornasier et al. (2015) (Tab. 3 therein), are overlaid. The applied Hapke model in Fornasier et al. (2015) has 5 parameters (single term Henyey-Greenstein func-

Figure 11: Phase curves for all experiments measured at $i = 0^\circ$ and $\lambda = 750 \text{ nm}$ before and after sublimation. a) Inter-mixtures in absolute reflectance, b) normalized at $\alpha = 5^\circ$, c) intra-mixtures in absolute reflectance, d) intra-mixtures normalized at $\alpha = 5^\circ$. All samples decrease in reflectance after sublimation in thermal vacuum. The intra-mixtures display a higher variation in shape when normalized than the inter-mixture. After sublimation the intra-mixtures have lower reflectances at high phase angles, which can be explained with a higher surface roughness or porosity.

tion, no coherent-backscattering mechanism) and is derived from disk-averaged
440 reflectance data.

The intra-mixture of experiment #3 before sublimation is the only sample having the highest reflectance factor at high phase angle, the initial intra-mixture of experiment #2 shows an almost flat phase curve from 30 to 80° phase
445 angle, #1 is as well u-shaped having almost the same REFF at $\alpha = 5^\circ$ and 80°. The phase curves of the inter-mixtures before sublimation of experiments #2 and #3 are monotonically decreasing, the one from #1 has a similar u-shape as the corresponding intra-mixture.

450 When analysing the normalized data the intra-mixtures show bigger changes in shape of the phase curves by sublimation than the inter-mixtures. The normalized reflectance at $\alpha = 80^\circ$ of the inter-mixtures decreases only by 20 % during the sublimation process of experiments #1 and #2, experiment #3 shows nearly no variation. The corresponding intra-mixtures show bigger variations at
455 this phase angle: Reflectance measured in experiments #1 and #3 decrease by 60 – 70 %, reflectance measured in experiment #2 with its rough, filamentous surface structure (see Fig. 3f) decreases by more than a factor of 2. This curve shows the highest coincidence with the cometary phase curve, which displays even lower relative reflectance at all phase angles, thought to originate from a
460 very porous surface structure of organics, silicates, other opaque minerals, and carbonaceous compounds (Jost et al., submitted; Feller et al., 2016).

Fig. 12 shows the same selection of phase curves as in Fig. 11, but measured at $i = 60^\circ$. Compared to vertical illumination, influences of macroscopic surface
465 roughness becomes more visible at higher incidence angles, where shadow cast can occur. All samples are significantly scattering in the forward direction (towards large phase angle), which is normally attributed to samples with low surface roughness (see Fig. 14 in Jost et al., 2013 for pure ice samples with different preparation methods). When normalized all samples have a higher

relative REFF at $\alpha = 120^\circ$ than at 5° , the relative decrease being again higher for the intra-mixtures than for the inter-mixtures. The calculated phase curve of 67P is strongly less forward scattering than our samples, nevertheless it has to be considered that the maximal phase angle achieved from OSIRIS data and used to fit the Hapke model was about 55° . Everything beyond is extrapolated. Further, the effects of large-scale roughness on the nucleus of 67P have to be considered, which can not be represented from cm-sized laboratory samples.

Figure 12: Phase curves of all experiments measured at $i = 60^\circ$ and $\lambda = 750\text{nm}$ before and after sublimation. a) Inter-mixtures in absolute reflectance, b) normalized at $\alpha = 5^\circ$, c) intra-mixtures in absolute reflectance, d) normalized at $\alpha = 5^\circ$. All samples decrease in reflectance after sublimation in thermal vacuum and become less scattering in the forward direction. The intra-mixtures display a higher variation in shape when normalized than the inter-mixtures. After sublimation the intra-mixtures have lower reflectances at high phase angles, which is consistent with a higher surface roughness or porosity.

All phase curves shown in this work are publicly available on the Data Analysis Center for Exoplanets (DACE) platform (<https://dace.unige.ch/lossy/>)

[samplesearch/index](#)) where they can be freely visualized and downloaded.

480 4. Discussion

In this section several fundamental characteristics such as brightness evolution, spectral slope and depth of absorption bands are discussed comparing the different experiments and samples. Further textural and structural evolution of experiment #3 is analysed in detail.

485

In order to study the evolution of brightness in the VIS spectral range, the reflectance of all experiments at 750 nm is plotted as a function of time in [Fig. 13](#). Experiment #2 has the most complete dataset with the best temporal resolution. The reflectance of its inter-mixture seems to decrease exponentially during 13 hours. The intra-mixture shows the same trend during the first 5 hours, then slightly increasing in brightness due to break-up of the residue matrix, exposing bright material at the surface. Afterwards it becomes re-surfaced and decreases in reflectance until the end of the experiment. The intra-mixture remains always darker than the inter-mixture. Experiment #1 shows a similar behaviour, the reflectance decreases non-linearly during 4 h, the intra-mixture is darker by $\sim 50\%$ in the beginning then the two converge towards similar reflectances. The decrease of experiment #3 follows a similar trend, after 4 h the inter-mixture is minimally brighter, then the reflectances of the two curves converge.

500

When analysing the reflectance from the phase curves in [Fig. 11](#), just after the initial sample preparation experiment #2 is the brightest, followed by #3 and #1. After sublimating in vacuum for several hours (see [Table 1](#)) samples from experiment #1 are the darkest, the ones from #3 the brightest, but the absolute differences in reflectance became smaller after sublimation. An unknown parameter on all experiments is the amount of trapped frost on samples surfaces during the BRDF acquisition. The sample holders were at a temperature of about -80°C when taken out from the SCITEAS chamber and then inserted to the PHIRE-2 freezer being operated at -35°C and $\sim 50\%$ of relative hu-

505

Figure 13: Evolution of the reflectance at 750 nm from all 3 experiments as a function of time. In all experiments the inter-mixture sample displays a higher reflectance than the intra-mixture. Experiment #1 started already at very low reflectance, after 4 h the reflectance of the two mixtures becomes very similar. Experiment #2 has the most complete dataset covering 13 h. The inter mixture displays an exponential decrease in reflectance with time, but remains always brighter than the intra-mixture associated to its yellowish colour. The intra-mixture from this experiment shows a subtle increase of reflectance at ~ 5 h, this is a consequence of redistributed residue layer material where pristine bright material gets exposed. Experiment #3 shows as well an exponential decrease of reflectance. The last point does not represent full 17 h of sublimation time, since the samples spent ~ 2 h at ambient pressure in the goniometer and a storage freezer.

510 midity. It is very likely that the outstanding rims of the aluminium sample holders, which have a much higher thermal inertia than the porous icy samples, caught most of the humidity before reaching thermal equilibrium. As visible in Fig. 6b the samples have a thin frost coating after the re-insertion into the SCITEAS chamber. It is not possible to infer, whether this frost was already
515 trapped inside the goniometer freezer or only by the insertion into SCITEAS when being exposed to room temperature between removing the cover and closing the chamber.

A basic feature of spectra is the slope between two wavelengths, we use the
520 same physical units as previously used in Fornasier et al. (2015) and in our companion paper (Jost et al., submitted). In Fig. 14 the relative spectral slope in the 550 – 910 nm range is plotted as a function of time. The relative spectral slope in units of %/100 nm is calculated as:

$$S[\%/100nm] = \frac{(R_{910} - R_{550})}{R_{550} \times (910nm - 550nm)} \times 10^4 \quad (1)$$

525 There seems to be a problem in absolute calibration of the SCITEAS imaging system, observing at a phase angle of 13°. The dry tholin/charcoal powder (identical to the non-volatiles in the icy samples of this experiment) measured in experiment #2 displays a relative spectral red slope of ~ 21 %/100nm, while the same sample material measured by the PHIRE-2 goniometer has a rela-
530 tive slope of ~ 6 %/100nm at the corresponding phase angle. PHIRE-2 has been proven to have a very accurate absolute calibration compared to other instruments and photometric reference targets (see e.g. Pommerol et al., 2011). Despite the problematic absolute calibration, the individual measurements during the sublimation experiment are fairly reliable as the time sequence of the
535 relative spectral slope from the (non-volatile) dry tholin/charcoal powder has a standard deviation as low as 0.57 %/100nm. This means that the relative spectral slope measured by hyperspectral imaging system is too high by a factor

of 3 but stable during all measurements. Further analysis of this issue will be necessary to fully understand these instrumental differences, and to accurately
 540 calibrate our data in absolute scale.

In all experiments the intra-mixtures have a higher relative spectral slope, i.e. they are redder, in units of % per 100 nm, than the corresponding inter-mixtures at a specific time. All samples are becoming redder with time as the
 545 (bluer) water ice component disappears. As shown in Figs. 5 to 7 the intra-mixtures are always darker than the corresponding inter-mixtures. This might explain the differences in Fig. 11. Data of experiments #1 and #2 are fitted by linear functions. The rates of change of the mixtures from experiment #2 seem very similar (0.8 vs. 1.0 %/h), the ones from the other two experiments
 550 are more uncertain due to the low number of data points.

Figure 14: Relative spectral slope in units of % per 100 nm in the 550 – 910 nm spectral range. The horizontal green line represents the spectral slope of a pure charcoal/tholin powder (90 %:10 %) which is the same composition as mixed with the icy samples in experiments #2 and #3. This powder was measured simultaneously during experiment # 2, the 20 datapoints were averaged, having a standard deviation of 0.57 %/100nm. Experiments #1 and #2 are fitted with a linear function, experiment #3 contains only 2 valid points, as the sublimation process was interrupted by ~ 2 h. In all experiments the intra-mixtures have a higher spectral slope than the corresponding inter-mixtures at a specific time.

To determine the amount of ice in the uppermost layer of the samples, the

depth of the water absorption band is a good indicator. The spectrum of tholins and charcoal shows no absorption bands at the same wavelengths. The band
 555 depth is calculated as follows:

$$\text{Band depth} = 1 - \frac{\text{reflectance}_{\text{band}}(\lambda)}{\text{reflectance}_{\text{cont.}}(\lambda)} \quad (2)$$

The reflectance at the band centre is divided by the reflectance of the continuum, connecting the adjacent local reflectance maxima (see illustration in Fig. 9) at the same wavelength. The measured band depths at 1.51 and 2.02 μm are
 560 plotted as a function of time in Fig. 15. The depth as well as the rate of change seem very similar for the two bands. The behaviour of experiment #2, which has a much higher initial albedo, appears different from the other experiments. It shows a clear difference between the band depths of intra- and inter-mixture at the beginning of the experiment, the inter-mixture showing deeper bands.
 565 After about 10 h the difference seems to vanish as the almost linear trends converge. The rates of changes of the darker samples from experiments #1 and #3 are by a factor of 2 – 3 steeper compared to experiment #2. Extrapolations would lead to a total disappearance of water ice bands after 5 – 6 h of sublimation time. This would be in general agreement with VIRTIS observations on
 570 67P where the majority of surface areas does not show any evidence of water ice absorption features in the spectrum (Capaccioni et al., 2015), exceptions are bright spots (Barucci et al., 2016) and areas affected by diurnal recondensation cycles (De Sanctis et al., 2015).

575 After removing the samples from the vacuum chamber at the end of experiment #3 a qualitative structural examination was performed to investigate the thickness of residue layer and solidification of sample material. At the stage of production all the samples had a powdery consistence with a low sintering and low cohesion tendency. It is well known that icy materials always strive
 580 to lower the total surface energy of the system and therefore reduce the total

Figure 15: a) Band depths of the 1.51 μm absorption band of water ice relative to a continuum at this wavelength, b) band depth at 2.02 μm as a function of time. All samples show a decreasing trend of band depth, corresponding to a lower amount of water ice exposed at the surface. The rate of change from experiments #1 and #3 are similar while experiment #2 has a lower rate due to its higher initial reflectance. The water ice band depth is mainly influenced by the carbon particles and not by the tholins which are nearly transparent in the NIR. In all experiments the inter-mixtures have a higher band depth than the intra-mixtures at a specific time, which is consistent with their slightly higher reflectance.

surface area by sintering of particle. Different transport mechanisms, such as vapour transport, are involved in this morphological change strongly dependent on temperature and pressure conditions (for more details see [Jost et al., 2013](#) and references therein). [Poch et al. \(2016a,b\)](#) found that during sublimation experiments the inter-mixtures showed more consolidation throughout the entire bulk while intra-mixtures formed a hard crust below the residue mantle but the underlying material was still soft.

The examination of experiment #3 was carried out by hand with a spatula cooled to liquid nitrogen temperature. The sample structure of pure ice was still quite loose without strong sintering effects, the upper part was slightly harder. The inter-mixture sample had built up a non-volatile mantle of ~ 1 mm in the illuminated area, where some material was ejected, and ~ 2 mm in the non-illuminated area. The texture of the mantle is powdery. Underneath the remaining ice was moderately hardened without a specific crust or vertical variation. The intra-mixture sample was covered by a residue layer of comparable

thickness, but the mantle showed more internal cohesion and larger structures. The ice underneath formed a distinct, harder crust in the uppermost third of the bulk, but was still powdery below. The coarse-grained intra-mixture kept its granular surface texture from the beginning and formed no clear residue layer. It seemed that the porous mantle formed locally around big individual grains/agglomerates. Below the first monolayer of agglomerates (~ 2 mm) a porous matrix of bright ice grains was found. Overall the sample was hardly sintered. These findings combined with the observation that on the coarse-grained intra-mixture only single particles were ejected or re-distributed across the surface lead to the interpretation that sublimation took place down to deeper layers or even the entire bulk. The rough structure allows gas flow from deeper layers to reach the surface through a network of voids and channels. The smoother texture and more uniform grain size distribution of the normal intra-mixture is more impermeable to gas flow and allows sublimation only within the uppermost ice particle layer. This leads to the formation of a mantle layer which is more uniform in thickness and has therefore a more uniform impermeability which leads to more severe outbursts.

5. Summary & Conclusion

In a series of laboratory investigations three sublimation experiments were performed and characterized with the SCITEAS and PHIRE-2 setups. These experiments under controlled laboratory conditions highlight the necessity of combining spectroscopy and bidirectional reflectance techniques in order to infer details about material composition as well as surface structure.

It was found that the two mixing types have slightly different spectra in the VIS range, the inter-mixtures generally being more yellowish have a more concave shaped spectrum and a higher reflectance. This is interpreted as a very efficient coating capability on nm-sized, orange-coloured tholin particles. In the NIR range the effects of mixing types are smaller as tholins are rather

transparent in this spectral range. The biggest differences in terms of mixing types are observed on surface texture, gas driven activity and bulk consolidation. The intra-mixtures formed a filamentous, very porous matrix with high cohesion, resulting in higher gas impermeability and more violent ejection events. 630 The residue of inter-mixture is more powdery, having lower cohesion producing smaller scaled ejections. This more compact residue mantle leads to enhanced downward flow of sublimation gas, recondensating in deeper layers. Thus the bulk gets more consolidated by recondensation.

635 We demonstrated the combined use of our two instrumental setups, SCITEAS and PHIRE-2, in all three experiments. The BRDF of unaltered samples was measured before inserting them in thermal vacuum during 6 – 14 h for sublimation under simulated space conditions. Afterwards the BRDF was measured again, showing reduced reflectance and lowered forward scattering behaviour, 640 consistent with lower ice content and a more porous surface.

During experiment #3 we have also demonstrated the integration of a solar simulator in our setup. The irradiation of the samples with visible light led to a different sublimation activity compared to the thermal IR flux reaching the 645 samples from the window of the chamber.

Spectroscopic analysis on all samples showed disappearing signatures of water ice in the NIR with time as the ice sublimed. This led as well to an increase of relative spectral slope in the VIS, i.e. the samples became redder, and the 650 reflectance at 750 nm decreased.

All VIS-NIR imaging data from the nucleus of 67P acquired by Rosetta is affected by the composition and structure of the uppermost micrometres, as passive methods in this spectral range cannot penetrate deeper. A better understanding how the physical parameters, such as composition and structure of 655 a refractory layer influences the observed spectra and phase curves is vital for

remote sensing data interpretation.

Our experimental simulations have shown how the sublimation process leads
660 to an ice-poor residue covering the underlying bulk material, the residue is completely masking any spectral signatures of water ice even when the total ice content in the bulk was more than 50 %. We showed how the way of mixing ice and non-volatiles can influence the porosity of this residue as well as the consolidation of ice below. This interface between a porous refractory layer and the more
665 primordial material underneath may play an important role in the creation of the very hard surface crust as measured by the MUPUS (Multipurpose Sensors for Surface and Sub-Surface Science) instrument on Philae ([Spohn et al., 2015](#)). Further laboratory experiments with longer timescales and additional methods for quantification will be needed to answer this question.
