The Presence of an Iron-Sulfur Cluster in Adenosine 5'-Phosphosulfate Reductase Separates Organisms Utilizing Adenosine 5'-Phosphosulfate and Phosphoadenosine 5'-Phosphosulfate for Sulfate Assimilation*

Received for publication, March 5, 2002, and in revised form, April 4, 2002 Published, JBC Papers in Press, April 5, 2002, DOI 10.1074/jbc.M202152200

It was generally accepted that plants, algae, and phototrophic bacteria use adenosine 5'-phosphosulfate (APS) for assimilatory sulfate reduction, whereas bacteria and fungi use phosphoadenosine 5'-phosphosulfate (PAPS). The corresponding enzymes, APS and PAPS reductase, share 25–30% identical amino acids. Phylogenetic analysis of APS and PAPS reductase amino acid sequences from different organisms, which were retrieved from the GenBank™, revealed two clusters. The first cluster comprised known PAPS reductases from enteric bacteria, cyanobacteria, and yeast. On the other hand, plant APS reductase sequences were clustered together with many bacterial ones, including those from Pseudomonas and Rhizobium. The gene for APS reductase cloned from the APS-reducing cyanobacterium Plectonema also clustered together with the plant sequences, confirming that the two classes of sequences represent PAPS and APS reductases, respectively. Compared with the PAPS reductase, all sequences of the APS reductase cluster contained two additional cysteine pairs homologous to the cysteine residues involved in binding an iron-sulfur cluster in plants. Mössbauer analysis revealed that the recombinant APS reductase from Pseudomonas aeruginosa contains a [4Fe-4S] cluster with the same characteristics as the plant enzyme. We conclude, therefore, that the presence of an iron-sulfur cluster determines the APS specificity of the sulfate-reducing enzymes and thus separates the APS- and PAPS-dependent assimilatory sulfate reduction pathways.

For all living organisms, sulfur is an essential element with many different functions. It is found in reduced form in amino acids, peptides, and proteins and in iron-sulfur clusters, lipic acid, and other cofactors and in oxidized form as sulfate group-modifying proteins, polysaccharides, and lipids. Reduced sulfur compounds, such as hydrogen sulfide, serve as electron donors for chemotrophic or phototrophic growth in a large and diverse group of Archaea and bacteria, including purple and green sulfur bacteria (1). On the other hand, oxidized sulfur compounds such as sulfate can function as a terminal electron acceptor in respiration to support the growth of sulfate-reducing bacteria (2).

The majority of sulfur in living organisms is present in the reduced form of organic thiols. For their synthesis, inorganic sulfate is reduced and incorporated into bioorganic compounds in a pathway named assimilatory sulfate reduction. Before reduction, sulfate is activated with ATP to adenosine 5'-phosphosulfate (APS), which can subsequently be converted into phosphoadenosine 5'-phosphosulfate (PAPS) using a second ATP. Either form of activated sulfate can be reduced to sulfite and reduced further to sulfide by sulfite reductase. Sulfide is incorporated into an activated amino acid acceptor, such as O-acetylserine, O-acetylhomoserine, or O-succinylhomoserine, to form cysteine or homocysteine (3–5).

The assimilatory sulfate reduction pathway is present in plants, fungi, and yeast and in a wide range of eubacteria but is missing in metazoa. It was generally accepted that chemotrophic bacteria and fungi utilize PAPS for reduction to sulfite in a reaction catalyzed by a thioredoxin-dependent PAPS reductase, whereas photosynthesizing organisms reduce APS directly (3–9). The boundary line between APS- and PAPS-utilizing organisms was not sharply defined, however, because among phototrophic bacteria and cyanobacteria, both APS- and PAPS-reducing species were described (8, 9). The plant APS reductase (APR), recently cloned from Arabidopsis thaliana, is a protein composed of two distinct domains: an N-terminal part is homologous to the Escherichia coli PAPS reductase (encoded by the cySH gene) and a C-terminal part is similar to thioredoxin with a function modified toward glutaredoxin (10–12). This enzyme is identical to the previously described APS sulfotransferase (13) and contains a [4Fe-4S] iron-sulfur cluster as a cofactor (14). APS reductase is a highly regulated enzyme, and it is considered to have a major control on the flux through assimilatory sulfate reduction in plants (3, 15).

1 The abbreviations used are: APS, adenosine 5'-phosphosulfate; APR, adenosine 5'-phosphosulfate reductase; PAPS, phosphoadenosine 5'-phosphosulfate; T, tesla.
However, the plant APS reductase is completely unrelated to the dissimilatory APS reductase found in both sulfate-reducing and sulfide-oxidizing bacteria and archaea (16, 17). This dissimilatory APS reductase (EC 1.8.99.2) catalyzes both the reduction of APS to sulfite and the oxidation of sulfite and AMP to APS. This enzyme is a 1:1 heterodimer of a 75-kDa FAD-binding α-subunit and a 20-kDa β-subunit binding two [4Fe-4S] centers (16). Also, the electron paramagnetic resonance spectral properties of the iron-sulfur clusters from both types of APS reductase are completely different (14, 16).

Very recently, a third type of APS reductase was identified in several sulfate- assimilating bacteria, such as *Pseudomonas, Rhizobium, Ralstonia, Burkholderia,* and *Allochromatium vinosum* (18–20). This novel enzyme is homologous to the PAPS reductase from *E. coli* and is even more homologous to the N-terminal part of plant APS reductase. However, the enzyme is missing the C-terminal part of the protein and requires thioredoxin as an electron donor. The major difference between these bacterial APS reductases and PAPS reductase from *E. coli* or *Salmonella typhimurium* is the presence of two additional cysteine pairs as in the plant enzyme (Fig. 1). Three of these Cys residues bind the FeS center in the plant APS reductase (14). From this finding, two questions arise: 1) does the bacterial assimilatory APS reductase contain an iron-sulfur center? and 2) are the additional Cys residues a marker for distinguishing APS- and PAPS-dependent sulfate reduction?

**EXPERIMENTAL PROCEDURES**

**Materials**—[^35]S]APS was prepared from[^35]S][SO₄] (Hartmann Analytic) according to Li and Schaff (21) with recombinant ATP sulfurylase from *A. thaliana*[^2] and inorganic pyrophosphatase (Sigma) (21). Oligonucleotide primers were synthesized at Microsynth GmbH (Balgach, Switzerland).

**Phylogenetic Analysis**—The GenBank™ and The Institute for Genomic Research databases were screened with the BLAST program. All of these proteins are characterized by a highly conserved (KT)[ECG(LI)H] motif (Fig. 1) containing a catalytically active Cys residue (32, 33). In addition, a number of related proteins of unknown function were found in several archaeabacteria, including *Methanococcus jannaschii, Pyrococcus horikoshii,* and *Pyrococcus abyssi.* These large proteins contained segments of ~200 amino acids that were 22–27% identical with both plant APS reductases and PAPS reductase of *E. coli* preceded by a 150–200-amino acid domain with no homology to other proteins. Because these proteins did not contain the essential (KT)[ECG(LI)H] motif, and because the APR-similar domain showed a 20–25% identity also with the CysD subunit of ATP sulfurylase from enteric bacteria, these archaea proteins were not included in the analysis.

**Results**

**Evolutionary Relationships of APS and PAPS Reductase**—To characterize the evolutionary relationships among APS- and PAPS-reducing enzymes, we used the sequence of the N-terminal domain of APR2 from *A. thaliana* to retrieve related sequences from the GenBank™ and The Institute for Genomic Research databases by the BLAST program. All of these proteins were characterized by a highly conserved (KT)[ECG(LI)H] motif (Fig. 1) containing a catalytically active Cys residue (32, 33). In addition, a number of related proteins of unknown function were found in several archaeabacteria, including *Methanococcus jannaschii, Pyrococcus horikoshii,* and *Pyrococcus abyssi.* These large proteins contained segments of ~200 amino acids that were 22–27% identical with both plant APS reductases and PAPS reductase of *E. coli* preceded by a 150–200-amino acid domain with no homology to other proteins. Because these proteins did not contain the essential (KT)[ECG(LI)H] motif, and because the APR-similar domain showed a 20–25% identity also with the CysD subunit of ATP sulfurylase from enteric bacteria, these archaea proteins were not included in the analysis.

Fig. 2 shows a neighbor-joining tree of APS and PAPS reductase-related sequences. The phylogenetic tree is divided into two major branches. The first branch contains a cluster of APS reductases from plants and algae, together with several bacterial enzymes; the other one was subdivided into clusters comprising fungal PAPS reductases and well-characterized APS reductases from enteric bacteria and cyanobacteria. However, such a tree topology does not reflect the phylogenetic relationships based on the 16 S rRNA genes. Only the Gram-positive bacteria, fungi, and β-proteobacteria appeared to be monophyletic. In contrast, two species of α-proteobacteria were found outside of the major α-proteobacterial group clustered with β-proteobacteria and *A. vincenti,* a γ-proteobacterium. Only γ-proteobacteria could be found in both major branches of the phylogenetic tree. The sequences of the new bacterial assimilatory APS reductases from *Rhizobium, Ralstonia, Burkholderia,* and *Pseudomonas* were all positioned on the major cluster containing the plant APS reductases. Also, the sequence of *CysH* from *Acidithiobacillus ferroxidans,* which most probably encodes an APS reductase (34), was found in this cluster. Although the overall bootstrap support of the neighbor-joining tree topology was only around 50%, phylogenetic analysis using the protein parsimony method resulted in a maximum parsimony tree with an almost identical topology (data not shown).

We hypothesized, therefore, that the nod separating the two major branches in this phylogenetic tree represents the border between APS- and PAPS-reducing species, respectively.

To test this hypothesis, we cloned and sequenced part of the gene for putative APS reductase from an APS-reducing cyanobacterium, *Plectonema* strain 73110 (8). We predicted that

[^2]: S. Kopriva, unpublished observations.
the position of the *Plectonema* enzyme in the phylogenetic tree would be in the same branch as plant APS reductases and assimilatory APS reductases from *Pseudomonas* and *Rhizobium*, but not as the PAPS reductases from other cyanobacteria, *Synechococcus*, and *Synechocystis*. Indeed, as shown in Fig. 2, the *Plectonema* APS reductase clusters with that of *P. aeruginosa* close to the plant APR proteins. This result indicated that, indeed, solely from the sequence of the cysH gene and its position in the phylogenetic tree, one could predict the sulfonucleotide specificity of the corresponding protein.

**Biological Characterization of APS Reductase from *P. aeruginosa***—A closer examination of the APS and PAPS reductase sequence alignment used for the phylogenetic analysis revealed that the major difference between sequences in the two branches is the presence of two strictly conserved Cys residues in the APS-reducing enzymes (compare Fig. 1). These Cys pairs were proposed to coordinate an FeS cluster in plant APS reductases (14). It was thus plausible to expect the same function in the prokaryotic enzymes. Therefore, the APS reductase from *P. aeruginosa* was overexpressed in *E. coli* by the pET expression system and purified as a yellow-brown protein, similar to the recombinant APR from *Arabidopsis* (14). The recombinant protein displayed an APS reductase activity of 2.1 pmol min⁻¹ mg⁻¹ protein when thioredoxin was omitted from the reaction mixture (Table I). Consequently, 3.2 pmol mg⁻¹ protein were determined in the *P. aeruginosa* APS reductase. On the other hand, similar to previous reports (32), the recombinant PAPS reductase from *E. coli* was isolated as a colorless protein without bound iron (Fig. 3).

To prove indisputably that the *Pseudomonas* enzyme also contains the iron-sulfur cofactor, Mössbauer spectroscopy, which in experiments with the plant APR turned out to be the method of choice (14), was used. The spectra were essentially identical with those obtained with the plant protein (14). The Mössbauer spectrum of *P. aeruginosa* APR obtained at 4.2 K in a small field of 20 mT (perpendicular to the γ-beam; Fig. 4a) exhibited an asymmetric quadrupole doublet. This asymmetry indicates that the iron sites in the cofactor are structurally different. Applying a strong field of 7 T (perpendicular and parallel to the γ-beam; Fig. 4, b and c) at 4.2 K showed that the iron sites form a diamagnetic cluster. This information, together with the isomer shift δ and the quadrupole splitting ΔEQ of the asymmetric doublet, which takes the values 6.0–4.5 mm s⁻¹ and ΔEQ = 1.2 mm s⁻¹ (see below), strongly points to the presence of [4Fe-4S]²⁺ clusters (31). The quantitative analysis of the measured spectra was based on the assumption that, as in the plant enzyme, only three Cys residues were binding to the metal cluster (14). It was assumed that three iron sites exhibit the same δ and ΔEQ values, which, however, may differ from the corresponding values of the fourth site. Thus, the fit comprises two doublets with an area ratio of 3:1.

Two different fits have been performed in view of the fact that the asymmetry of the quadrupole doublet (Fig. 4a) could be accounted for by two symmetric doublets with either (I) δ1 = δ2 = ΔEQ1 ≠ ΔEQ2, or (II) δ1 ≠ δ2, ΔEQ1 ≠ ΔEQ2.

With start parameters corresponding to case (I) and (II), respectively, the obtained parameter sets are as follows: (I), δ1 = 0.46 mm s⁻¹, ΔEQ1 = 1.02 mm s⁻¹ (75%), δ2 = 0.43 mm s⁻¹, and ΔEQ2 = 1.34 mm s⁻¹ (25%); and (II), δ1 = 0.49 mm s⁻¹, ΔEQ1 = 1.09 mm s⁻¹ (75%), δ2 = 0.33 mm s⁻¹, and ΔEQ2 = 1.14 mm s⁻¹ (25%).

Because the two cases yield practically the same goodness of fit, only the results for case (I) have been presented in Fig. 4. Both parameter sets were used to simulate the magnetic pattern of the spectra measured at a magnetic field of 7 T (Fig. 4, b and c). Again, there is no obvious preference for either case.

**DISCUSSION**

The properties of APS reductase from *P. aeruginosa* are very similar to those of the C-terminally truncated plant APR, lacking the thioredoxin-like domain (12, 14, 19, 33). The enzyme produces sulfite from APS but not from PAPS, and the activity is stimulated by thioredoxin m but is not absolutely dependent on this compound. The reported Vmax of the *Pseudomonas* APR, 5.8 μmol min⁻¹ mg⁻¹ (19), is almost identical to that of the N-domain of APR from *Arabidopsis*, 5.1 μmol min⁻¹ mg⁻¹, and the reduction of the iron sites is therefore likely to occur through the solution pathways rather than the protein. Further biochemical analysis of the *P. aeruginosa* APR revealed that the enzyme possesses a diamagnetic [4Fe-4S]²⁺ cluster at the ac-
Assimilatory APS Reductase in Bacteria

The previously described assimilatory APR from Sinorhizobium meliloti (18) also contains the FeS cofactor, as revealed by the dark yellow-brown color of the recombinant protein and the fact that the enzyme binds 4 nmol Fe/nmol protein (data not shown). Remarkably, dissipatory APRs of sulfate-reducing bacteria and archaeabacteria, such as Desulfovibrio and Archaeoglobus, respectively (35, 36), or sulfur-oxidizing phototrophic bacterium A. vinosum (37) also contain [4Fe-4S] centers, although these enzymes are not otherwise related to the assimilatory enzymes. The role of the iron-sulfur cluster in the reaction mechanism of assimilatory APRs is not clear, but nevertheless, it seems that the ability to reduce APS is linked to the presence of an iron-sulfur cluster in the enzyme.

These findings have far-reaching implications for understanding the evolution of sulfate assimilation. In contrast to earlier reports (6–9), the results reported previously (18–20, 34) and presented here demonstrate that APS-dependent assimilatory reduction of sulfate is not connected to oxygen-evolving photosynthesis but is present in a large range of eubacterial taxa. From the bacterial species included in the phylogenetic analysis (Fig. 2), preferential reduction of APS over PAPS was confirmed in the γ-proteobacteria Pseudomonas, A. ferrooxidans (34), and A. vinosum (9); β-proteobacteria Burkholderia and Rhodobacter (19); and α-proteobacteria S. meliloti and R. tropici (18). Furthermore, because no homologues of APS kinase are present in the completely sequenced genomes of Neisseria meningitidis (β-proteobacteria) and Geobacter sulfurreducens (δ-proteobacteria), one can conclude that these species also possess an APS reductase. In the neighbor-joining tree, the CysH sequences of all these species are found within the large cluster containing the plant APR sequences (Fig. 2). In addition to the species mentioned above, three subclusters are part of the individual Fe subsites is different from the other three because it is either tetragonally FeS₃X-coordinated, with X being a non-sulfur ligand (C, N, O) or trigonally sulfur-coordinated.

the tentative APR cluster: the Archae, Firmicutes, and α-proteobacteria. In these organisms, either both APS and PAPS reductase activities were measured or nothing is known about the sulfonucleotide utilized for reduction (9, 19). The hypothesis that this large cluster represents APS reductases was strengthened by the cloning of the CysH gene from the APS-reducing cyanobacterium *Plectonema*. Whereas the previous reports and experiments confirmed the APS-dependent activity predicted from the position of the corresponding sequences in the phylogenetic tree, a known enzymatic activity was the starting point in this case (8). Indeed, as expected, the *Plectonema* APR was clustered together with the APS-reducing enzymes of *Pseudomonas* and not with the other cyanobacteria that form a small subcluster in the PAPS reductase cluster of the phylogenetic tree (Fig. 2). Because all enzymes from the tentative APR cluster contain the two additional Cys pairs (Fig. 1), which, in at least four species, bind an iron-sulfur cofactor that seems to be essential for reduction of APS, we conclude that these Cys pairs might serve as a marker for distinguishing between APS- and PAPS-dependent reductases.

The first bacterial species in which sulfate assimilation was investigated were the enterobacteria *E. coli* and *S. typhimurium* (4). The sulfate assimilation in these species requires synthesis of PAPS. PAPS-dependent sulfate reduction was also observed in yeast (5) and several cyanobacteria (8); in contrast, plants, algae, and phototrophic bacteria utilized APS directly (6–9). It was thus believed that the APS pathway was dependent on oxygen-evolving photosynthesis and that the PAPS pathway was ubiquitous in nonphotosynthetic bacteria (3, 38). However, the results presented here indicate that the PAPS pathway in prokaryotes is restricted to only a few groups of γ-proteobacteria and cyanobacteria. Because APS-reducing species are also found among cyanobacteria and γ-proteobacteria, a horizontal gene transfer must have played an important role in today’s distribution of the two enzyme activities (39). Interestingly, the evolution of dissimilatory APR reductase was also affected by frequent horizontal gene transfers (40). An important question arises: was the ancestral sulfate assimilation APS- or PAPS-dependent? The APS reductase pathway seems to be the original one because: 1) APS reductase was present in the evolutionary ancient sulfate-reducing bacteria and Archaea, 2) the reduction via APS requires one ATP less than that via PAPS, and 3) the domains similar to APS and PAPS reductase in the archaeabacterial proteins, e.g. the *M. jan-nashii* hypothetical protein MJ0973 (GenBank™ accession number Q58383) or *P. horikoshi* PH0268, contain the Cys residues required for the coordination of an iron-sulfur cluster (41).

Using protein signature sequences, a linear succession was proposed in which the various phyla evolved from a common ancestor in the following order: *Firmicutes, Deinococcus/Thermus* group, cyanobacteria, *Spirochetes, Aquificales + Chlamydiales + green sulfur bacteria, ε-δ-proteobacteria, α-proteobacteria, β-proteobacteria, and γ-proteobacteria (42, 43). If the original gene encoded an APS reductase, the distribution of the reductases can be easily explained by assuming the evolution of PAPS reductase after separation of γ-proteobacteria and a single horizontal gene transfer event into the cyanobacteria. On the other hand, if the original gene encoded PAPS reductase, the evolution of APS reductase would have to occur several times independently, or the horizontal gene transfer would have taken place at least four times. Obviously, the former scenario is more plausible; therefore, we conclude that the APS reductase pathway is the original pathway of sulfate assimilation. Why there are two pathways of sulfate reduction in bacteria still remains an open question. The evolution of a PAPS reductase, which does not need the iron-sulfur cluster, might have been an adaptation to an iron- and/or sulfur-poor environment or to increasing concentrations of oxygen in the atmosphere because the iron-sulfur center is unstable in air. However, an evolutionary advantage of one pathway over the other remains to be shown, as discussed for the dissimilatory APR in *A. vinousum* (44).

Plant APS reductase comprises three domains: a chloroplast-targeting peptide, an APS reductase part, and a C-terminal thioredoxin-like domain. The gene thus most probably originated from a fusion between genes for APS reductase and thioredoxin. Because all APRs isolated or cloned from higher plants, as well as the APR from the green algae *Enteromorpha intestinalis* (45), have the same structure, this fusion must have occurred early in the evolution of plants. The close relation of the *Plectonema* APS reductase to the plant enzymes also implies that plants obtained the gene for APS reductase from the chloroplast ancestor. As discussed above, the ancient sulfate assimilation pathway in cyanobacteria was most probably APS-dependent; therefore, the gene acquired by the original symbiont would be that of APS reductase. The cyanobacterial gene was then allocated to the plant nuclear genome through endosymbiotic gene transfer and supplemented with the sequence encoding the targeting peptide, such as genes coding, e.g. for Calvin cycle enzymes (46).
