

# CPAP as treatment of sleep apnea after stroke

## A meta-analysis of randomized trials

## Abstract

### Objective

To perform a systematic review and meta-analysis of randomized controlled trials (RCTs) examining the effectiveness of continuous positive airway pressure (CPAP) in stroke patients with sleep disordered breathing (SDB).

### Methods

In a systematic literature search of electronic databases (MEDLINE, Embase, and the Cochrane Library) from 1980 to November 2016, we identified RCTs that assessed CPAP compared to standard care or sham CPAP in adult patients with stroke or TIA with SDB. Mean CPAP use, odds ratios (ORs), and standardized mean differences (SMDs) were calculated. The pre-specified outcomes were adherence to CPAP, neurologic improvement, adverse events, new vascular events, and death.

### Results

Ten RCTs (564 participants) with CPAP as intervention were included. Two studies compared CPAP with sham CPAP; 8 compared CPAP with usual care. Mean CPAP use across the trials was 4.53 hours per night (95% confidence interval [CI] 3.97–5.08). The OR of dropping out with CPAP was 1.83 (95% CI 1.05–3.21,  $p = 0.033$ ). The combined analysis of the neurofunctional scales (NIH Stroke Scale and Canadian Neurological Scale) showed an overall neurofunctional improvement with CPAP (SMD 0.5406, 95% CI 0.0263–1.0548) but with a considerable heterogeneity ( $I^2 = 78.9%$ ,  $p = 0.0394$ ) across the studies. Long-term survival was improved with CPAP in 1 trial.

### Conclusion

CPAP use after stroke is acceptable once the treatment is tolerated. The data indicate that CPAP might be beneficial for neurologic recovery, which justifies larger RCTs.

## Glossary

**AHI** = apnea-hypopnea index; **CI** = confidence interval; **CNS** = Canadian Neurological Scale; **CPAP** = continuous positive airway pressure; **NIHSS** = NIH Stroke Scale; **OSA** = obstructive sleep apnea; **PRISMA** = Preferred Reporting Items for Systematic Reviews and Meta-Analyses; **RCT** = randomized controlled trial; **SDB** = sleep disordered breathing.

Sleep disordered breathing (SDB) with an apnea-hypopnea index (AHI) >15/h is present in ≈26% of the general population and a common comorbidity in stroke survivors.<sup>1-3</sup> The reported prevalence after stroke varies between 50% and 70%, depending on the chosen cutoff for the AHI and time lag from stroke, but it is consistently higher in acute stroke patients than in the general population.<sup>4,5</sup> SDB can improve after the acute stroke phase, but up to 60% of the patients still show an AHI >10/h and 30% show an AHI >30/h ≈3 months after the stroke or TIA.<sup>1,2,4</sup> Most of the stroke patients have obstructive sleep apnea (OSA), which has been identified as an independent risk factor for stroke and is associated with a higher mortality.<sup>6-9</sup>

Treatment of OSA with continuous positive airway pressure (CPAP) leads to improvements in sleepiness and cognitive performance in the general population, but the data on the prevention of cardiovascular or cerebrovascular disease<sup>10-13</sup> and its effects on neurologic recovery after stroke<sup>14</sup> are still conflicting. Identifying and treating OSA in stroke survivors was added to the American Heart Association/American Stroke Association stroke guidelines in 2014 with a Class IIb recommendation and Level of Evidence B.<sup>15</sup> However, the timing of diagnostic investigations and treatment initiation has not been specified, and unlike other independent risk factors for stroke, e.g., arterial hypertension or dyslipidemia, which are usually identified and treated in stroke patients within the first days after hospital admission, the treatment of SDB is still often neglected.<sup>16</sup> Concerns include the feasibility and effectiveness of CPAP in the acute setting, which might partially explain the large number of undiagnosed and untreated patients and delays between admission for stroke and start of OSA treatment.<sup>4,17</sup>

In addition to nonrandomized observational studies with matched control groups, more randomized controlled trials (RCTs) using CPAP have been published recently in stroke cohorts. Thus, the objective of the present study was to systematically review and analyze the literature on treatment of SDB in adult patients after TIA or stroke with regard to acceptance of CPAP and its effectiveness to modify clinical outcome parameters.

## Methods

This systematic review and meta-analysis is reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.<sup>18</sup>

### Search strategy

We performed a systematic search of MEDLINE, Embase, and the Cochrane Library between January 1980 and

November 2016 to identify RCTs comparing CPAP with sham CPAP or usual care to treat SDB in adult patients after a TIA or stroke. The full list of search terms is included in tables e-1 through e-3 ([links.lww.com/WNL/A320](http://links.lww.com/WNL/A320)). To identify additional trials, we examined reference lists of the identified articles, relevant reviews in the field, and clinical trial registries.

### Study selection

Study selection was performed in duplicate by 2 independent authors (A.-K.B., T.H.). Disagreement was resolved by discussion with a third author (A.S.). The titles and abstracts of identified publications were screened, and potentially relevant articles were retrieved for a full-text review. A full list of inclusion and exclusion criteria is given in table e-4 ([links.lww.com/WNL/A320](http://links.lww.com/WNL/A320)). In short, inclusion was restricted to full-text RCTs comparing CPAP with sham CPAP or usual care to treat SDB in adult patients after a stroke or TIA. There were no language restrictions. We excluded duplicate publications, all study designs other than RCTs, abstracts, conference communications, and other interventions to treat SDB.

### Data extraction

The prespecified outcomes for the meta-analysis were nightly use (adherence), reduction of AHI compared to baseline; dropouts; improvement of the NIH Stroke Scale (NIHSS), Canadian Neurological Scale (CNS), or other neurofunctional and cognitive parameters<sup>19</sup>; adverse events related to the intervention; new vascular events; and mortality (table e-4, [links.lww.com/WNL/A320](http://links.lww.com/WNL/A320)). If multiple reports were available for 1 trial, we used information of all reports for data extraction but extracted outcome data only once on the basis of completeness and follow-up.

All data were extracted independently and in duplicate (A.-K.B., T.H.) for each included RCT with a standardized prespecified data collection form. If multiple follow-up time points were present, the longest follow-up was considered. Studies were divided into early treatment, defined as treatment onset within 7 days after a cerebrovascular event, and delayed treatment, starting >7 days after TIA or stroke. We contacted the authors of all RCTs to obtain additional individual patient data on neurologic outcomes.

### Assessment of risk of bias

The quality of each included RCT was assessed with the Cochrane risk of bias tool, which covers 6 domains of bias: selection bias, performance bias, detection bias, attrition bias, reporting bias, and other bias.<sup>20</sup> For each RCT, 2 reviewers (A.-K.B., T.H.) independently assigned a score of high, low, or

unclear quality for each domain. Disagreement was resolved by discussion with a third author (M.C.).

## Statistical analysis

Mean CPAP use per night (compliance), odds ratios of dropping out of the trial, and standardized mean differences (expressed as the Hedge  $g$ ) in NIHSS and CNS scores were combined in DerSimonian-Laird random-effects meta-analysis. Heterogeneity was assessed with  $I^2$  statistics, with  $I^2$  values of  $>50\%$  considered as substantial heterogeneity and  $I^2 >75\%$  as considerable heterogeneity.<sup>21</sup> We intended to assess publication bias using funnel plot techniques, the Begg rank test, and the Egger regression test, as appropriate. We used the meta package in R (version 3.3.2; R Foundation for Statistical Computing, Vienna, Austria) for all analyses.<sup>22,23</sup> Results are presented as estimates with 95% confidence intervals (CIs).

## Results

### Search results

From 2,880 publications that were retrieved by the literature search, we identified 27 studies (30 full-text publications) with interventions to treat SDB after TIA or stroke (figure 1 and table e-5, [links.lww.com/WNL/A320](https://links.lww.com/WNL/A320)). Ten studies were RCTs using CPAP to treat OSA to improve post-TIA or poststroke outcomes in adults and were included in the meta-analysis (table 1).

### Study characteristics

The included RCTs that randomized a total of 564 participants with TIA or clinically or imaging-confirmed stroke. Four RCTs provided information on stroke subtypes according to the etiology or the vascular territory<sup>24–27</sup>; 1 RCT differentiated between hemorrhagic and ischemic stroke.<sup>28</sup> In 7 RCTs, prediagnosed or already treated SDB was an exclusion criterion. The other 3 studies did not provide information on preexisting SDB.<sup>25,29,30</sup> Mean baseline AHI ranged from 11/h to 38.5/h and depended on the study-specific inclusion criteria (table e-5, [links.lww.com/WNL/A320](https://links.lww.com/WNL/A320)).<sup>26,31</sup> Three studies did not assess AHI at inclusion because of immediate initiation of CPAP and a delayed performance of the diagnostic polysomnography.<sup>25,32,33</sup> Studies were performed in acute care hospitals or in rehabilitation units with study durations and follow-ups varying between 8 days and 5 years. The sample size varied between 30 and 140 participants.

In 5 trials, treatment was started early within 7 days after stroke. The other 5 studies initiated treatment 10 to 28 days after the cerebrovascular event (table e-5, [links.lww.com/WNL/A320](https://links.lww.com/WNL/A320)). Details of the individual study characteristics are provided in table 1 and table e-5.

### Assessment of risk of bias

The individual risk of bias in the 10 RCTs was mixed with an overall high risk of bias for blinding of participants in

the open-label studies and a lower risk in the more recent trials (table e-6, [links.lww.com/WNL/A320](https://links.lww.com/WNL/A320)).<sup>24,28,31</sup> Publication bias was not assessed because there were inadequate numbers of included trials to properly assess a funnel plot or more advanced regression-based assessments.

### Reduction of AHI, dropouts, and compliance

Information on the reduction of AHI with CPAP was reported in 3 studies and reached a mean AHI of  $<10/h$ .<sup>24–26</sup>

Dropouts and adherence to CPAP were evaluated in all trials. Dropout rates ranged from 0% to 46%, with more dropouts in the CPAP groups than for sham CPAP or usual care. There were more dropouts in the trials starting CPAP early. The combined odds ratio of dropping out was 1.83 (95% CI 1.05–3.21,  $p = 0.033$ ) with no between-study heterogeneity ( $I^2 = 0\%$ ) (figure 2).

Seven RCTs reported a mean CPAP use of  $\geq 4$  hours a night, and 2 had a mean CPAP use  $<4$  hours a night, resulting in a combined mean CPAP use of 4.53 hours a night (95% CI 3.97–5.08), but with considerable heterogeneity ( $I^2 = 87.2\%$ ,  $p < 0.0001$ ) across the studies (figure 3 and table 1). CPAP use and heterogeneity were similar in the subgroup analysis ( $p = 0.0631$ , early CPAP  $I^2 = 84.0\%$ , delayed CPAP  $I^2 = 84.2\%$ ). One study with a reported low adherence could not be included in the meta-analysis because of insufficient data in the publication and no reply from the authors.<sup>29</sup>

Factors associated with poor adherence were neurologic impairment, mask discomfort, depressive symptoms, or subjective sleep disturbance.<sup>29,30</sup> None of the RCTs assessed a potential association between excessive daytime sleepiness or preexisting SDB and subsequent CPAP use.

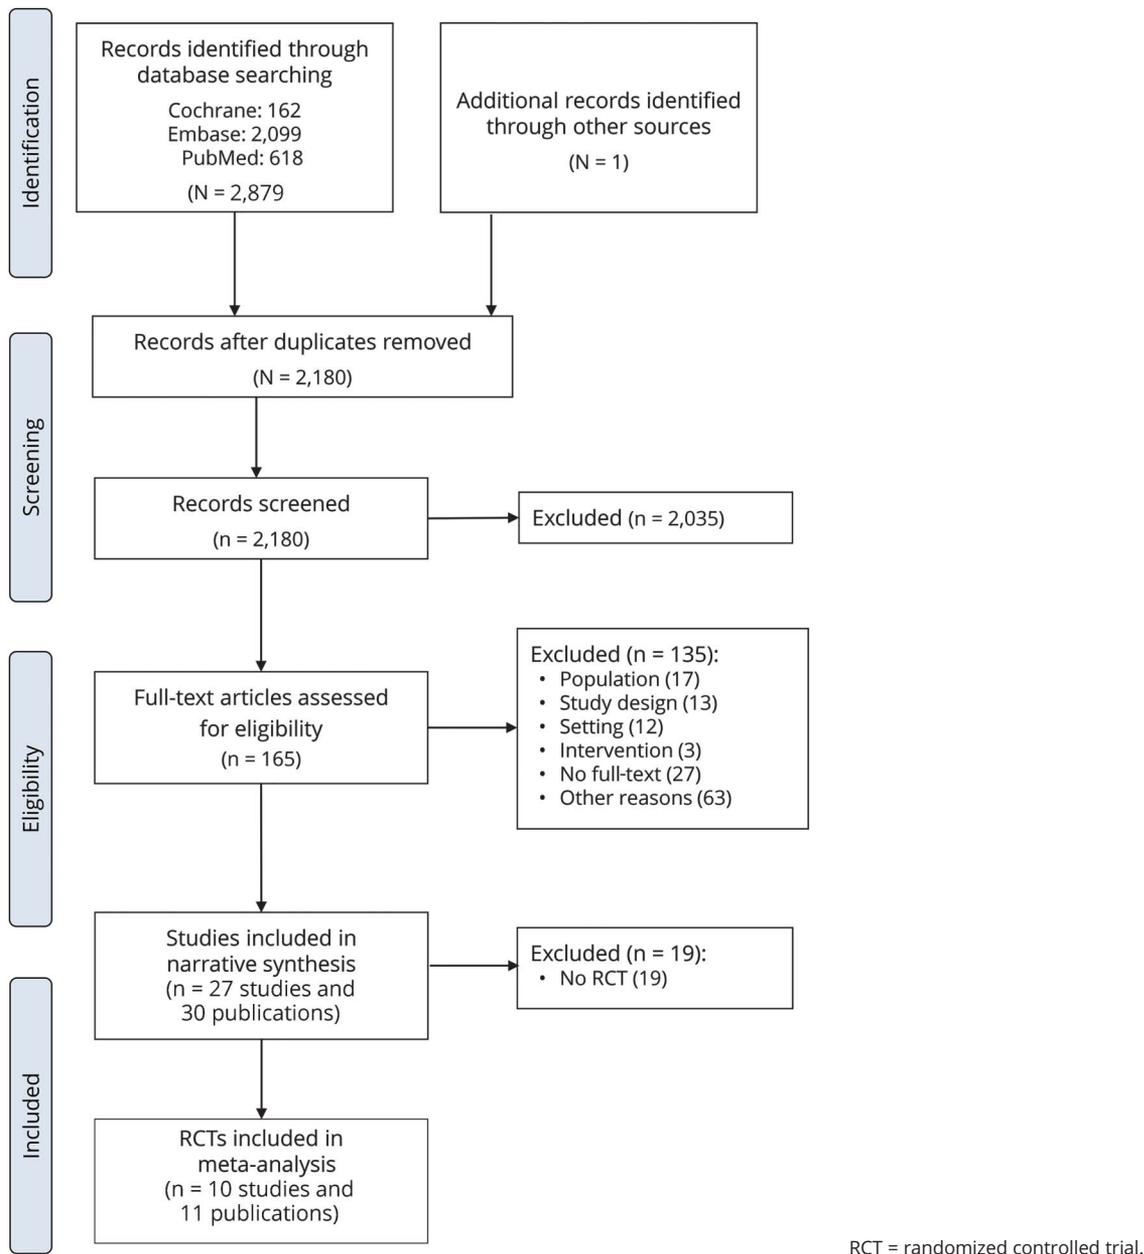

### Adverse events

Four RCTs reported details on adverse events.<sup>26,27,32,33</sup> Serious adverse events not related to the study intervention were mentioned in the 2 studies without differences between CPAP and controls (patients with TIA: CPAP, 7 events in 45 participants [15.6%], and controls, 4 events in 25 participants [16%]; stroke patients: CPAP, 2 events in 31 patients [6.5%], and controls, 5 events in 24 participants [20.8%]).<sup>32,33</sup> There were no serious adverse events related to CPAP. Nonserious adverse events were more frequent in the CPAP groups and were related mainly to the mask (e.g., facial marks or dry noses).<sup>32,33</sup>

### Neurofunctional outcomes

Neurofunctional changes were assessed in 6 RCTs with the NIHSS and CNS at baseline and follow-up. In 2 studies, the NIHSS score was available only for baseline or follow-up<sup>28,31</sup>; 1 study assessed patients with TIA only<sup>32</sup>; and 1 study did not provide NIHSS or CNS scores.<sup>30</sup> Independence scales were the Barthel Index, modified Rankin Scale, Functional

**Figure 1** PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram of study retrieval

Independence Measure score, or Utrecht Scale for Evaluation of Rehabilitation.

Additional individual patient data on the NIHSS or CNS and independency scales were provided by 5 authors.<sup>24–27,33</sup> In the combined analysis of the neurofunctional scales (NIHSS and CNS) of these 5 studies and 1 study with original data from the publication,<sup>29</sup> the standardized mean difference showed overall a neurofunctional improvement with CPAP with a standardized mean difference of 0.5406 (95% CI 0.0263–1.0548). The heterogeneity of the studies was high with  $I^2 = 78.9%$  ( $p = 0.0394$ ) and a  $z$  test of 2.06 ( $p = 0.0394$ ) (figure 4), and

subgroup analyses of early and delayed CPAP trials showed nonsignificant changes. Independency scales remained unchanged within the individual studies. An individual correction of the neurofunctional or independency scores for adherence was not realizable. However, a greater improvement in NIHSS score was mentioned in patients with a better adherence to CPAP in 2 publications.<sup>25,33</sup> The results were not affected by the stroke subtypes.

### Neurocognitive functions, depression, and sleepiness

Because of different scales and heterogeneity of the reported data, a meta-analysis of these outcomes was not possible.

Abbreviations: AHI = apnea-hypopnea index; BMI = body mass index; CPAP = continuous positive airway pressure; RCT = randomized controlled trial; UC = usual care. Data are presented as ranges, mean ± SD, or median (interquartile range) unless otherwise indicated.

<sup>a</sup>The 95% confidence interval.

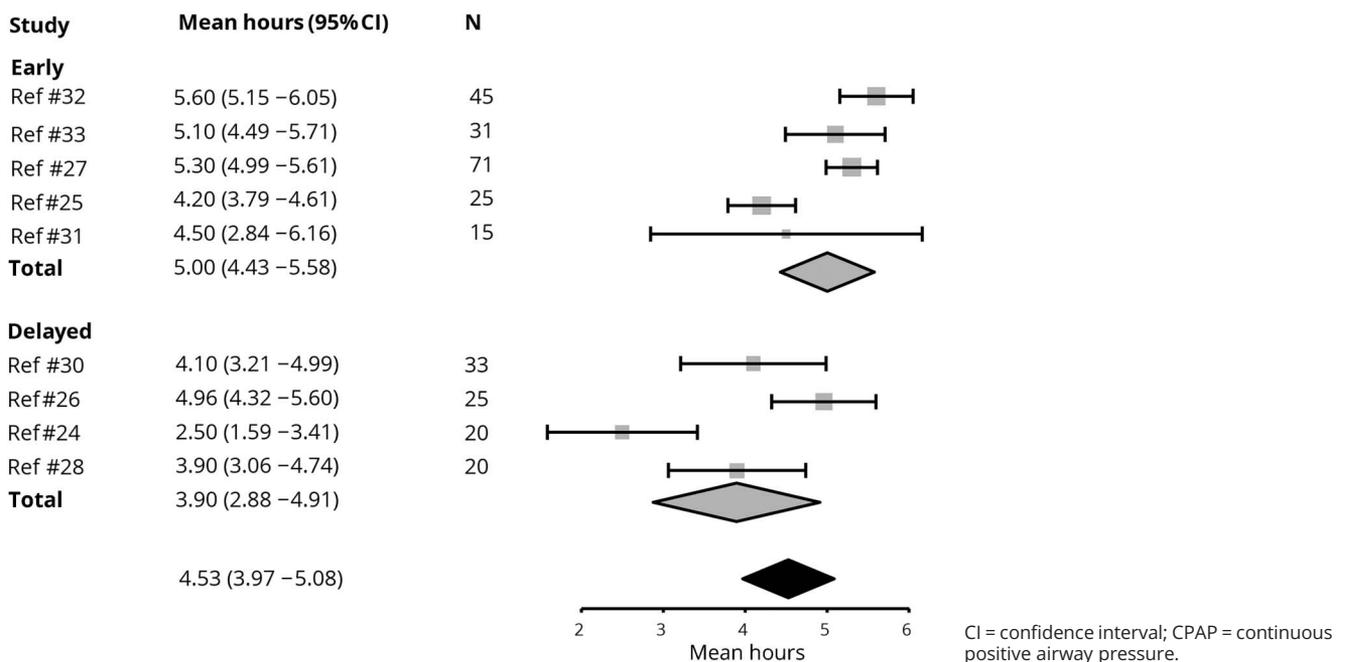

**Figure 2** Forest plot representing the probability to drop out (random-effects model)

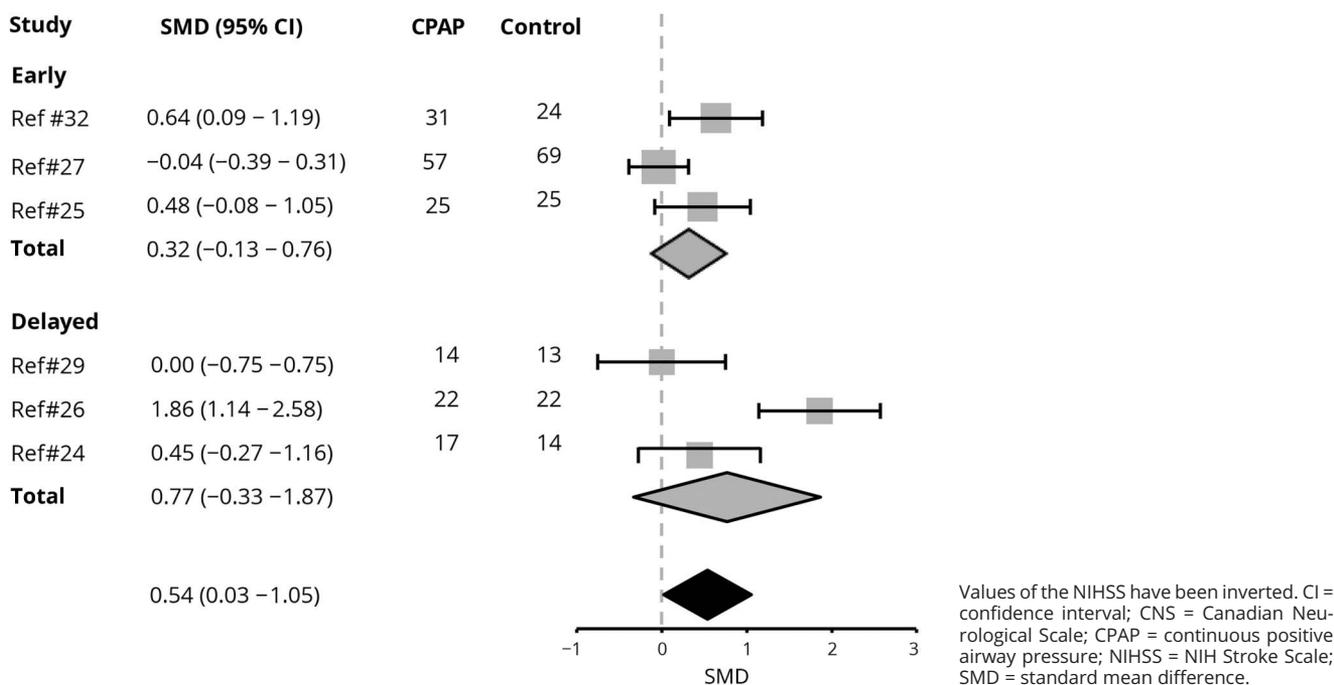

There was an improvement in neurocognitive tests in the intention-to-treat analyses in the CPAP group in the 2 most recent RCTs,<sup>24,28</sup> while there were no significant differences in standard cognitive screening tests in others.<sup>29,30</sup> Three trials assessed depressive symptoms,<sup>26,30,31</sup> and 2 found an

improvement in favor of the CPAP treatment.<sup>26,30</sup> Findings on sleepiness were inconsistent: 2 RCTs, one of them starting CPAP in the acute setting, did not find a difference,<sup>33,34</sup> whereas the third trial found significant differences in favor of CPAP.<sup>26</sup>

**Figure 3** Forest plot representing the adherence to CPAP treatment in hours per night (random-effects model)

**Figure 4** Forest plot representing SMDs and 95% CIs (random-effects model) of NIHSS and CNS

### New vascular events and mortality

Two RCTs with early CPAP found no significant differences in the few combined vascular events (recurrent TIA, stroke, myocardial infarction, hospitalization for congestive heart failure, death) that were recorded within the studies, but the trials were neither long enough nor sufficiently powered for this outcome.<sup>32,33</sup> An improvement in cardiovascular survival compared to usual care was found in a long-term follow-up over 5 years.<sup>34</sup> In this RCT, CPAP compared to usual care was associated with a longer time to the next cardiovascular event (14.9 vs 7.9 months), but there was no significant difference in the overall cardiovascular event-free survival, and the generalizability of these findings is limited by a small sample size.<sup>27,34</sup>

### Discussion

This meta-analysis shows that adherence to CPAP treatment, once tolerated, is acceptable in stroke survivors with SDB in the acute and more chronic setting. The overall adherence of study participants of 4.5 hours a night seems remarkable because compliance to CPAP is already a difficult issue in the general SDB population and is even more challenging in neurologically impaired stroke survivors and the particularly difficult environmental circumstances of stroke units. However, this high adherence rate has to be interpreted with caution and needs to be balanced against the fact that most of the RCTs were designed as feasibility studies with short and variable durations of the intervention and heterogeneous follow-up intervals. The difficult recruitment of stroke

patients and their high dropout rates in clinical trials were also seen in the trials included in this meta-analysis, even in the newer RCTs.<sup>35</sup> Early dropouts were not considered for the analysis in most RCTs, which may also bias the reported adherence rates and lead to an overestimation. In addition, the number of rather mildly affected patients might have been higher in the RCTs than it is to be expected in routine practice.

CPAP treatment was judged as safe across the trials, and no serious adverse events related to the intervention were reported. Similar to CPAP trials in the general population, nonserious adverse events, related to the mask, were more frequent in the CPAP groups and would probably be acceptable if a beneficial treatment effect could be demonstrated.

SDB after ischemic stroke is believed to contribute to neural damage and a worse stroke outcome by affecting the perfusion and oxygenation of the penumbra.<sup>7,11,36</sup> In theory, the early application of CPAP may therefore contribute to a longer survival of the penumbra and result in clinically and radiologically measurable neurologic improvements. Short-term neuroimaging effects have not been investigated sufficiently in the available trials, but in terms of the neurofunctional outcomes, a recent review and meta-analysis on noninvasive ventilator correction in patients with acute ischemic stroke postulated a positive association of noninvasive ventilator correction and short-term neurologic improvement.<sup>37</sup> This meta-analysis included only 2 small RCTs and 1 observational study with a matched control group in the analysis of the

neurologic outcome, which explains the low heterogeneity but also weakens the significance of their findings. Our analysis included more studies and additional individual patient data, and the subgroup analysis of the included early treatment initiation trials showed no significant difference between CPAP and the comparator. This indicates the need for a larger sample size to evaluate whether CPAP is really beneficial for early neurologic recovery.

A delayed start of CPAP might not be able to influence the penumbra anymore, but because SDB contributes independently to cognitive dysfunction, sleepiness, and depression, a positive treatment effect on these components could lead to a better participation in the rehabilitation program and support the recovery from stroke.<sup>36</sup> Despite the statistically significant result across all 6 included trials favoring CPAP, the subgroup analysis of neurofunctional change of the delayed starting RCTs also remained nonsignificant.

CPAP adherence led to better neurologic outcomes in 2 RCTs, which is in line with adherence analyses performed for the effect of CPAP on blood pressure that showed treatment results in favor of CPAP.<sup>38</sup> Thus, an adequate adherence might be essential for further CPAP trials in stroke survivors.

There was only 1 RCT with a long-term follow-up over 5 years, which showed a longer cardiovascular event-free survival with CPAP.<sup>34</sup> This matches the findings of the largest available observational study in this field, which also found a reduction of cardiovascular events in stroke patients treated with CPAP.<sup>39</sup> Considering data from the general population, a beneficial influence of CPAP on vascular prognosis could also be expected in patients with neurologic sequelae.<sup>9,11,12</sup> However, the available data are not sufficient to confirm this hypothesis.

The overall significant positive result on the neurofunctional outcome (figure 4) has to be interpreted with caution because of several limitations. The analysis and comparability of the included studies are limited by the high dropout rates and small sample sizes, as well as a relevant heterogeneity across the RCTs due to methodologic differences (partial blinding, onset of treatment, follow-up duration, and outcome parameters) and, to a lesser, extended clinical diversity (inclusion of AHI, TIA vs stroke). We tried to account for this by using random-effects models for our analyses, and because of the available heterogeneous datasets, we used both NIHSS and CNS changes to increase the sample size for the assessment of the neurologic outcome and contacted authors for individual patient data. Because there is no defined minimal, clinically important difference regarding the improvement in NIHSS and CNS, a more appropriate outcome assessment would have included the analysis of independency scales such as the Barthel Index. A meta-analysis of these scales could not be performed because of insufficient data.

The data on CPAP treatment after stroke are promising. However, because of the heterogeneity and limitations of the

currently available trials, the data are not sufficient to draw confident evidence-based conclusions about the beneficial effects on neurologic and cognitive outcomes or long-term survival. Apart from clinical scales and neurocognitive testing, further trials with well-predefined outcome parameters should also focus on imaging methods and include a larger number of patients. Further RCTs are required to clarify the place of CPAP in the treatment of SDB after stroke.

# CPAP as treatment of sleep apnea after stroke

## A meta-analysis of randomized trials

### Study question

Do existing randomized controlled trials (RCTs) support the efficacy of continuous positive airway pressure (CPAP) in stroke patients with sleep-disordered breathing (SDB)?

### Summary answer

Existing RCTs indicate that CPAP may aid neurologic recovery in stroke patients with SDB.

### What is known and what this paper adds

Obstructive sleep apnea (OSA), which is a form of SDB and a common comorbidity in stroke patients, can be effectively treated with CPAP in the general population, but studies in stroke patients have yielded conflicting results. This meta-analysis provides evidence supporting the efficacy of CPAP in aiding neurologic recovery in stroke patients with SDB.

### Design, size, and duration

This study began with a systematic search of Medline, Embase, and the Cochrane Library for RCTs published between January 1980 and November 2016 that compared CPAP to either sham CPAP or usual care in patients with SDB and either TIA or stroke. RCT bias was assessed with the Cochrane Risk of Bias Tool.

### Participants and setting

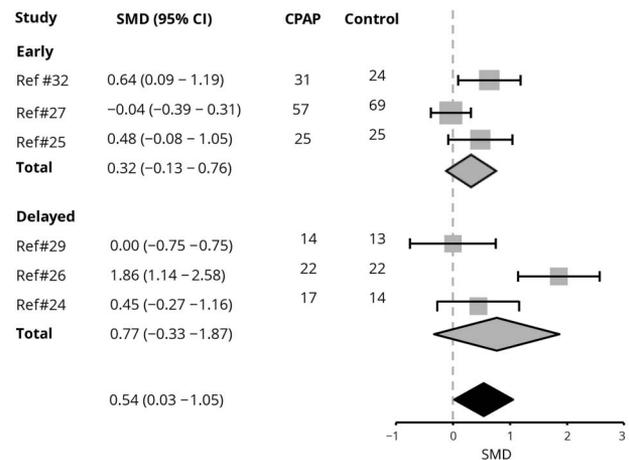

The meta-analysis examined 10 RCTs published between 2001 and 2016 with a total of 564 participants with OSA following either TIA or stroke. In total, the CPAP, sham CPAP, and usual care groups included 300, 37, and 227 participants. The settings included acute care hospitals and rehabilitation units.

### Primary outcomes

The primary outcome was the overall neurofunctional improvement with CPAP as measured with either the NIH Stroke Scale (NIHSS) or the Canadian Stroke Scale.

### Main results and the role of chance

NIHSS or Canadian Stroke Scale data were available for 6 RCTs (166 CPAP group participants; 167 control group

participants). The standardized mean difference for neurofunctional improvement with CPAP was 0.5406 (95% confidence interval 0.0263–1.0548), but the heterogeneity across studies was considerable ( $I^2 = 78.9\%$ ;  $p = 0.0394$ ).

### Bias, confounding, and other reasons for caution

The RCTs had high participant withdrawal rates and relatively small sample sizes. Few of the RCTs had matched control groups. Methodologic inconsistencies resulted in high heterogeneity. The minimum clinically important improvements on the NIHSS and Canadian Stroke Scale are undefined.

### Generalizability to other populations

The RCTs might have disproportionately included patients with mild symptoms. This would limit generalizability to patients with severe symptoms.

### Study funding/potential competing interests

This study was funded by the Swiss National Science Foundation. The authors report no competing interests. Go to [Neurology.org/N](http://Neurology.org/N) for full disclosures.

A draft of the short-form article was written by M. Dalefield, a writer with Editage, a division of Cactus Communications. The authors of the full-length article and the journal editors edited and approved the final version.
