Asymptotically Exact Unweighted Particle Filter for Manifold-Valued Hidden States and Point Process Observations

Simone Carlo Surace, Anna Kutschireiter, and Jean-Pascal Pfister

Abstract—The filtering of a Markov diffusion process on a manifold from counting process observations leads to 'large' changes in the conditional distribution upon an observed event, corresponding to a multiplication of the density by the intensity function of the observation process. If that distribution is represented by unweighted samples or particles, they need to be jointly transformed such that they sample from the modified distribution. In previous work, this transformation has been approximated by a translation of all the particles by a common vector. However, such an operation is ill-defined on a manifold, and on a vector space, a constant gain can lead to a wrong estimate of the uncertainty over the hidden state. Here, taking inspiration from the feedback particle filter (FPF), we derive an asymptotically exact filter (called ppFPF) for point process observations, whose particles evolve according to intrinsic (i.e., parametrization-invariant) dynamics that are composed of the dynamics of the hidden state plus additional control terms. While not sharing the gain-times-error structure of the FPF, the optimal control terms are expressed as solutions to partial differential equations analogous to the weighted Poisson equation for the gain of the FPF. The proposed filter can therefore make use of existing approximation algorithms for solutions of weighted Poisson equations.

I. INTRODUCTION

A LARGE number of natural and engineered systems and datasets have states that are naturally described as elements of smooth manifolds. Classical cases are the motion of a body constrained by equality constraints, motion on the surface of the earth, or the attitude of a rigid body. Increasingly, the systems are very high-dimensional, whereas data points often lie on relatively low-dimensional manifolds, whose structure can be exploited for filtering and estimation problems.

In filtering, the state of the system (called the hidden state) needs to be estimated from the history of observations. In practice, observations often arrive sparsely, randomly and in digital form. One example is when observations are simple event counts. Such counting or point process observations arise in a variety of applications of time series models, e.g., neuroscience, geosciences, or finance.

The exact solution of the filtering problem is intractable in most cases and requires numerical approximation. One approach has been the class of interacting particle algorithms, in which an unweighted ensemble of \( N \) particles is propagated based on the known dynamics of the hidden state and the incoming observations. The feedback particle filter (FPF) [1]–[2] is such an algorithm that is based on mean-field optimal control, with a gain×error structure that is reminiscent of the Kalman filter. The gain is given by the solution of a partial differential equation (PDE), which makes the FPF exact in the limit of large \( N \) even for nonlinear problems. Although in practice the gain has to be estimated from the particles, unweighted approaches hold the promise of scaling to high-dimensional problems, in contrast to particle algorithms with importance weights [3].

In this letter, we consider the problem of finding an FPF-like algorithm for systems whose hidden states evolve continuously in time on a known smooth manifold and observations are given by a conditional Poisson process. The FPF for manifold-valued hidden states and diffusion observations has been introduced in [4]. A filter for a hidden state in \( R^n \) and point process observations was introduced in [5], called EKSPF. While it is reminiscent of the FPF, having a gain×error structure, it uses a constant gain. As a result, the filter is exact only to first order and does not properly reflect higher-order statistics. For example, when particles are initially spread out and an incoming event confers evidence that the hidden state is in some narrow region of the state space, we should find the updated particles concentrated in that region. However, upon
reduction of uncertainty, and performs a scaling in addition to the trans-
variance. (b) By contrast, the optimal gain also takes into account the
control term associated to an event leads to a translation of all the particles by a common
vector. This leads to the correct mean but over-estimates the
ated to an event leads to a translation of all the particles by a common
vector.

Fig. 1. (a) In Euclidean space, a constant gain for the update associ-
ated to an event leads to a translation of all the particles by a common
translation vector. This leads to the correct mean but over-estimates the
variance. (b) By contrast, the optimal gain also takes into account the
translation vector. This leads to the correct mean but over-estimates the

The optimal gain should transform the particle ensemble such that it
is intrinsic, i.e., independent of the choice of coordinates. However, the filtering problem on a manifold
is difficult in extending the EKSPF to hidden states evolving
in-between events.

The remainder of this letter is structured as follows: in
Section II, we introduce the mathematical notation, review
the filtering problem for the Gaussian white noise observation
case, and re-derive the FPF in the manifold setting, making
some observations regarding the symmetry of the problem. In
Section III, we present our main contribution: we derive the
ppFPF, which is an adaptation of the FPF to point-process
observations. In Section IV, we present numerical examples
that illustrate the differences in performance and uncertainty
quantification (UQ) between the ppFPF and other filters.

II. PRELIMINARIES AND BACKGROUND

A. Notations and Conventions

Tangent vectors at a point \( p \in M \) are written in a local chart as \( d\theta|_p \), where Einstein’s summation convention is used. A
vector field \( X \in \text{Vect}(M) \) is a smooth section of the tangent
bundle \( TM \) and is written locally as a first-order differential
operator \( X\partial \). The Lie derivative with respect to the vector
field \( V \) is denoted by \( \mathcal{L}_V \) and acts on sections of tensor prod-
uct bundles of \( TM \). If \( \varphi \in \mathcal{C}^\infty(M) \), then its differential \( d\varphi \)
is a one-form or smooth section of the cotangent bundle \( T^*M \).
More generally, a differential form of degree \( k \) is a smooth
section of \( \Omega^k(M) := \bigwedge^k T^*M \), where the wedge denotes the
exterior product. Top degree forms are elements of \( \Omega^n(M) \),
where \( n \) is the dimension of \( M \). A nowhere-vanishing element
of \( \Omega^n(M) \) is an orientation; if such an element exists then \( M \)

an event the EKSPF translates all particles by the same vector,
see Figures 1a-1b.

The reliance on this uniform translation also leads to dif-
ficulties in extending the EKSPF to hidden states evolving
on a manifold. In fact, when the EKSPF is applied naïvely
on some arbitrary chart of the manifold, filtering performance
can be poor (see Section IV for an example). This is because
the meaning of a ‘translation’ is fundamentally ill-defined on
a manifold. Since a translation in coordinate chart \( A \) does not
necessarily correspond to a translation in coordinate chart
\( B \), the performance of the EKSPF depends on the choice of
coordinates. However, the filtering problem on a manifold
is intrinsic, i.e., independent of the choice of coordinates.
It would therefore be desirable for a particle filter, and the
transformation of particles in particular, to be defined in a
coordinate-independent way. This would be advantageous even
if the state space carries additional structure, such as the vector

space structure on \( \mathbb{R}^n \). A large class of estimation problems
in \( \mathbb{R}^n \), such as, e.g., satellite tracking, are naturally described
in curvilinear coordinates.

For infinitesimal motions of particles, the notion of constancy
of a vector field\(^1\) and thus of a constant gain approximation,
depends on additional structure on the manifold, namely a
connection; a mathematical structure that prescribes how to
parallel transport a vector between different points. This can be
visualised for the example of the unit circle \( S^1 \) that (regarded
as a smooth manifold) can be embedded in different ways
in, say, \( \mathbb{R}^2 \) (see Figures 1c-1f). If the constancy of a tan-
gent vector field is made to depend on the embedding, then
we obtain different vector fields for different embeddings. On
many manifolds, there are no nontrivial parallel vector fields,
which precludes the choice of a nontrivial constant gain. While
this problem also affects a constant gain approximation of
the FPF gain, the problem can be circumvented by seeking
a non-constant gain estimate. Meanwhile, the constant gain
assumption is ‘baked’ into the EKSPF.

In this letter, we derive an exact FPF-like filter on a man-
ifold for point process observations, called ppFPF, from first
principles, addressing the limitations of a constant gain in the
EKSPF. The result is a filter whose control terms are given
by solutions of PDEs analogous to the Poisson equation for
the gain of the FPF. However, the gain×error structure of the
FPF is not strictly preserved. Instead, for the conceptual rea-
sons stated above, the control term associated to an event is
fundamentally distinct and treated separately from the term
in-between events.

1As we will explain in the next section, the control terms in the FPF can
be viewed as vector fields.
is called orientable, and we can then distinguish positive top degree forms, which we call volume forms. Normalized volume forms will be used to describe smooth nowhere-vanishing distributions on \( M \). This letter \( d \) is used for exterior derivatives on differential forms \( \omega \in \Omega^k(M) \) as \( d \omega \), and for stochastic differentials on stochastic processes \( X_t \) as \( dX_t \). The interior derivative on \( \omega \in \Omega^k(M) \) wrt. \( X \in \text{Vect}(M) \) is written as \( \langle \omega, \xi \rangle \). The notation \( \mathcal{F}^t \) is used for the filtration generated by the process \( (Y_t)_{t \geq 0} \).

**B. Filtering Problem and Filtering Equations**

We consider a filtering problem in which the hidden state \( X_t \) evolves as a Markov diffusion process on an \( n \)-dimensional manifold \( M \), described by a Stratonovich stochastic differential equation (SDE) of the form

\[
dX_t^i = V_0^i \, dt + \sum_{j=1}^r V_j^i \circ dB_t^j,
\]

where \( V_0, V_1, \ldots, V_r \) are vector fields on \( M \). This is a second-order differential operator, which can be expressed in local coordinates as

\[
\mathcal{A} = V_0^i \partial_i + \frac{1}{2} \sum_{k=1}^r V_k^i \partial_i V_j^k.
\]

The classical observation model in nonlinear filtering is an infinitesimal generator \( \mathcal{A} \), which can be expressed in local coordinates as \( \mathcal{A} = V_0^i \partial_i + \frac{1}{2} \sum_{k=1}^r V_k^i \partial_i V_j^k \).

The problem thus is to specify dynamics for a representative particle \( S_t \), from which particle instance \( \hat{\mu}_t \) can be derived by an integration-by-parts argument using Lie derivatives:

\[
\begin{align*}
\frac{d}{dt} \phi \hat{\mu}_t &= \int_M (\mathcal{A} \phi \circ dY_t + \Omega \phi dt) \hat{\mu}_t \\
&= \int_M \phi \left( \mathcal{A} \hat{\mu}_t dt - \mathcal{L}_K \hat{\mu}_t \circ dY_t - \mathcal{L}_\Omega \hat{\mu}_t dt \right) + \text{boundary terms}.
\end{align*}
\]

In the first line, the Stratonovich chain rule is used. In the second line, directional derivatives are replaced by Lie derivatives, and we performed integration by parts, reducing exact top-degree forms to boundary terms using Stokes’ theorem. It is customary to demand that \( K, \Omega \) be tangent to the boundary of \( M \) (if \( \partial M \) is nonempty), or even completely vanish on \( \partial M \). This assumption implies \( \mathcal{L}_K \hat{\mu}_t = 0 \) on \( \partial M \), such that the boundary terms can be discarded. After switching back to Itô calculus, one obtains

\[
\begin{align*}
d\hat{\mu}_t &= \left( \mathcal{A} \mu_t - \mathcal{L}_\Omega \hat{\mu}_t + \frac{1}{2} \mathcal{L}_K^2 \hat{\mu}_t \right) dt - (\mathcal{L}_K \hat{\mu}_t) dY_t,
\end{align*}
\]

where \( \hat{\mu}_t = \int_M \mu_t \) and \( \mathcal{A}^* \) is the adjoint of \( \mathcal{A} \) with respect to the dual pairing \( \langle \mu_\psi \rangle \) of volume forms and smooth functions, i.e., for all bounded \( \varphi \in C^\infty(M) \) and all volume forms \( \mu \) we have

\[
\int_M \varphi \mathcal{A}^* \mu = \int_M (\mathcal{A} \varphi) \mu.
\]
Matching the terms of Eq. (8) with Eq. (4) (conditioned on \( \hat{\mu}_t = \mu_t \)) leads to the system of equations\(^5\)

\[
\mathcal{L}_K \mu_t = -(h - \hat{h}) \mu_t, \quad (9)
\]

\[
\mathcal{L}_\Omega \mu_t = \frac{1}{2} (h^2 - \hat{h}^2 - K_t \hat{h}) \mu_t. \quad (10)
\]

Given a vector field \( K_t \) solving Eq. (9), called a gain for the FPF, setting

\[
\Omega_t = -\frac{1}{2} (h + \hat{h}) K_t \quad (11)
\]
gives an associated solution to Eq. (10)\(^6\).

### E. Uniqueness, Approximation, and Estimation of the Gain

The solutions of Eqs. (9) and (10) are not unique, as any pair \((K_t, \Omega_t)\) of solutions can be modified by adding an arbitrary divergence-free\(^7\) vector field \( V \), i.e., such that \( \mathcal{L}_V \mu_t = 0 \).

Uniqueness can be obtained by fixing a Riemannian metric \( g \), and then demanding that the gain take the form \( K_t = \text{grad} \phi_t \). This leads to the equation \( \mathcal{L}_{\text{grad} \phi_t} \mu_t = -(h - \hat{h}) \mu_t \).

Moreover, if \( \text{vol}_g \) denotes the Riemannian volume form and \( \mu_t \) is expressed in terms of the density \( p_t \) as \( \mu_t = p_t \text{vol}_g \), Eq. (9) reduces to a (weighted) Poisson equation

\[
\text{div}_{\text{vol}_g} (p_t \text{grad} \phi_t) = -(h - \hat{h}) p_t. \quad (12)
\]

Existence and uniqueness of a solution is guaranteed under mild assumptions on \( p_t \) and \( h \) (see [7, Th. 2.2]), and \( K_t = \text{grad} \phi_t \) minimizes the functional \( K \mapsto \int_M g(K, K) \mu \) among all solutions of Eq. (9) (see [8, Lemma 8.4.2]). In the case \( M = \mathbb{R}^n \), Euclidean \( g \), Gaussian \( p_t \), and linear \( h \), this gain reduces to the Kalman gain.

Sometimes it is desirable to approximate the vector field \( K_t = \text{grad} \phi_t \), where \( \phi_t \) solves Eq. (12), by a constant. As mentioned in the introduction, in order to define the notion of constancy on a manifold, an additional structure \( \nabla \), called connection, has to be defined. One may choose the Levi-Civita connection corresponding to some (already given) \( g \), but other choices are possible. A constant gain \( K_{\text{CG}} \) can then be defined as the minimum of \( \| K - \text{grad} \phi^0 \| \) over all parallel \( K \) (i.e., \( \nabla K = 0 \)). For example, when \( M = \mathbb{R}^n \), \( g \) is the Euclidean metric, and \( \nabla \) its Levi-Civita connection,

\[
K_{\text{CG}} = \int_{\mathbb{R}^n} \text{grad} \phi(\mu) = \int_{\mathbb{R}^n} x(h(x) - \hat{h}) \mu(dx). \quad (13)
\]

The right-hand representation is obtained by multiplying the Eq. (12) by \( x \), integrating by parts, and using grad \( x \) instead of \( \text{grad} \).

\( \text{div}_{\text{vol}_g} \) is defined implicitly by \( \mathcal{L}_V \mu = (\text{div}_V) \mu \). Using Cartan’s magic formula and the fact that \( \text{div}_V = df(V) + f \text{div}_V \). It follows that for \( f > 0 \) we have \( f \text{div}_V = \left. \frac{d}{dt} \right|_{t=0} (f \text{ div}_V) = df(V) + f \text{div}_V \).

\( ^5\) \( K_t = \text{div}(hK_t) = \text{div}(\nabla h) \) denotes the directional derivative of \( h \) in the direction of the vector field \( K_t \), whereas \( hK_t \) is the vector field \( K_t \) scaled point-wise by the function \( h \).

\( ^6\) This can be shown by using Cartan’s magic formula and the graded product rule for the interior derivative, or simply by observing that \( \mathcal{L}_X \mu = \psi \mathcal{L}_X \mu + (X \psi) \mu \) for all \( \psi \in C^\infty(M) \), \( X \in \text{Vect}(M) \), and \( \mu \in \mathbb{P}\).

\( ^7\) The divergence of a vector field \( V \) with respect to a volume form \( \mu \) is the function \( \text{div}_V \mu \) defined implicitly by \( \mathcal{L}_V \mu = (\text{div}_V) \mu \). Using Cartan’s magic formula and the fact that \( \text{div}_V = df(V) + f \text{div}_V \). It follows that for \( f > 0 \) we have \( f \text{div}_V = \left. \frac{d}{dt} \right|_{t=0} (f \text{ div}_V) = df(V) + f \text{div}_V \).

In other cases the situation is still worse: many manifolds with connection do not have any nontrivial parallel vector fields (a common example is \( S^2 \) with its standard connection).

In practise, the gain \( K_t = \text{grad} \phi_t \) has to be estimated from a finite number of particles \( S_t^{(i)} \in M, i = 1, \ldots, N \), thought to be i.i.d. samples from \( \mu_t \). If only the gain at the particle locations is needed, we denote the mapping particles \( \rightarrow \) gains by \( K_t = \mathcal{C}(S_t, h) \), where \( K_t = ((K_t)^{(i)})_{i=1}^N \) and \( S_t = (S_t^{(i)})_{i=1}^N \). This is called the gain estimation problem. For the purposes of this letter, the question of how to optimally estimate the gain shall be left aside and we refer to, e.g., [9, 10, 11] and the references therein. The aim is to show that the construction of an FPF-like algorithm for point processes can be fully reduced to the same types of equations as for the FPF gain, i.e., to equations of the following form:

\[
\mathcal{E}(\mu, \phi): \quad \mathcal{L}_V \mu = -(\phi - \int_M \phi \mu) \mu, \quad (14)
\]

whose unknown quantity is the vector field \( V \).

### III. FPF for Point Process Observations

Now, we consider the case where the hidden state \( X_t \) is a diffusion on a manifold as in Section II, but the observation process is now a counting process\(^8\) \( N_t \), counting the number of events since time \( t = 0 \), with intensity function \( h(X_t) \), where \( h : M \rightarrow (0, \infty) \) is called the observation function. Here, the observations are corrupted by Poisson noise.

An equation for the optimal filter is known also in this setting. If the distribution of \( X_0 \) is described in terms of a volume form \( \mu_0 \), the conditional distribution \( \mu_t \) of \( X_t \) given observations \( \mathcal{F}_t \) evolves according to the equation

\[
d\mu_t = (\mu_t \mu_t) dt + \left( \frac{h}{h_t} - 1 \right) \mu_t (dN_t - \hat{h} dt), \quad (15)
\]

where \( \hat{t} \) denotes left limits. Eq. (15) will be referred to as the filtering equation for point process observations. It is sometimes called Kushner-Stratonovich-Poisson equation (see [5] for further references).

The goal of the present section is to carry out the derivation of an FPF for point process observations. We will call the resulting filter feedback particle filter for point process observations, or ppFPF for short.

In the following two subsections, we will separately derive the drift and the jump terms of the particle dynamics. The separation of these two aspects is necessary because the drift

\( ^8\) By convention, \( N_t \) is right-continuous with left limits (càdlàg).
term is infinitesimal, i.e., a vector field, whereas the event term is an instantaneous transformation of the particles from the prior to the posterior. Since a vector field (infinitesimal) and a finite transformation cannot be easily mixed, the ppFPF lacks the gain×error structure of the FPF, with a common prefactor. This will be shown below.

A. Derivation of the Drift Term

We first consider the terms proportional to $dt$ in Eq. (15), describing the evolution of the conditional distribution in-between events, and make the following ansatz for the particle dynamics:

$$dS_t = V_0 dt + V^j_t \circ dZ^j_t + \Omega_t dt.$$  \hspace{1cm} (16)

Since the modification is deterministic, the corresponding equation for the conditional distribution of $S_t$ given $\mathcal{F}_t$ simply reads

$$d\mu_t = \left( \mathbf{\mathcal{L}} \mu_t - \mathbf{\mathcal{L}} \mu_t \right) dt.$$  \hspace{1cm} (17)

Matching this to Eq. (15) again, setting $\mu_t = \mu_t$ yields the relation

$$\mathbf{\mathcal{L}} \mu_t = (h - \hat{h}) \mu_t,$$  \hspace{1cm} (18)

which is $\mathcal{E}(\mu_t, -h)$, up to a sign the same as Eq. (9) for the gain of the FPF. Thus, up to divergence-free terms, the drift of the ppFPF is identical to the negative gain of the corresponding FPF (i.e., with the same $h$).

B. Derivation of the Jump Term

Upon an event, Eq. (15) prescribes a change of the conditional distribution as follows:

$$\mu_t \mapsto \mu_t = \frac{h}{h_t} \mu_{t^-},$$  \hspace{1cm} (19)

i.e., the distribution is multiplied by the observation function and subsequently renormalized. This requires a corresponding instantaneous change of the particle positions, i.e., $S_t \mapsto S'_t = T_t(S_t)$, where $T_t: M \to M$ satisfies the constraint

$$(T_t)_* \mu_{t^-} = \frac{h}{h_t} \mu_{t^-},$$  \hspace{1cm} (20)

where $*$ denotes the pushforward. In rare cases, such as for Gaussian $p$ and exponential $h$, this functional equation has exact closed-form solutions. In the absence of an exact solution, a solution $T_t$ to Eq. (20) can be approximated by an iterative procedure, also used in [12], [13], by an adaptation of Moser’s classical result [14]. The idea is to define an interpolation of $\mu_t$ and $\hat{h} \mu_{t^-}$:

$$\tilde{\mu}_{t,s} = \frac{h^s}{h_t} \mu_{t^-}, \quad 0 \leq s \leq 1.$$  \hspace{1cm} (21)

We then match this flow of probability distributions with a flow of particles, i.e., the flow of an $s$-dependent vector field $V_{t,s}$ satisfying

$$\mathbf{\mathcal{L}}_{V_{t,s}} \tilde{\mu}_{t,s} = - \frac{d}{ds} \tilde{\mu}_{t,s} = - \left( \log h - \int_M (\log h) \tilde{\mu}_{t,s} \right) \tilde{\mu}_{t,s},$$  \hspace{1cm} (22)

which is equation $\mathcal{E}(\mu_{t,s}, \log h)$ in Definition 1. This procedure results in Algorithm 1.

C. Exactness of the Particle Filter

Thus, the ppFPF is defined in terms of the following dynamics, yielding a càdlàg process:

in-between events: $dS_t = V_0 dt + V^j_t \circ dZ^j_t + \Omega_t dt,$  \hspace{1cm} (23)

event at time $t$: $S_t = T_t(S^-) = T_t(S^-),$  \hspace{1cm} (24)

where $\Omega_t$ is a vector field that solves Eq. (18) and $T_t$ is the diffeomorphism constructed in Section III-B. The PDEs to be solved for both steps are of the forms $\mathcal{E}(\mu, -h)$ and $\mathcal{E}(\mu, \log h)$, and are therefore analogous to the PDE for the gain of the FPF. As a result, all considerations in Section II-E apply to the ppFPF. By construction, the ppFPF has the following property of being exact:

Theorem 1: Let $\mu_t$ denote the conditional distribution of $X_t$ given $\mathcal{F}_t$. Under assumption A, if the distribution of $S_0$ coincides with $\mu_0$, and if the process $(S_t)_{t \geq 0}$ is defined according to Eqs. (23)-(24), then the conditional distribution of $S_t$ given $\mathcal{F}_t$ coincides with $\mu_t$ for all $t \geq 0$.

was implemented with the differential loss reproducing kernel Hilbert space [15], ppFPF; this letter). Simulations used $dt = 0.01$ and were run for $10^5$ time-steps. BPF, EKSP, and ppFPF used $N = 200$ particles. The gain estimation method for the ppFPF used parameters $s = 10$ and $\lambda = 10^{-7}$. While all filters have comparable performance (first-order statistics), the uncertainty is more strongly under-estimated for the EKSPF and ADF compared to the asymptotically exact filters (BPF and ppFPF).

In this example, both performance and UQ is compromised for the EKSPF due to the conceptual reasons outlined in the introduction.

V. Conclusion

In this letter, we reviewed the problem of designing unweighted particle filters for a manifold-valued hidden process observed in Poisson noise. We provided conceptual arguments as well as numerical illustrations that the existing approach from [5] (EKSPF) is limited by an intrinsic constant gain approximation, which compromises higher-order statistics as well as the ability to be extended to manifolds. We then derived an asymptotically exact unweighted particle filter, called ppFPF, by matching the particle forward equation with the equation for the optimal filter. This approach starts from first principles and is analogous to the derivation of the FPF. The resulting filter does not have the gain error structure of the FPF, but can otherwise be reduced to partial differential equations that are completely analogous to the ones in the FPF. This makes it possible to leverage existing and future approaches to gain estimation in the FPF. As an unweighted filter, the ppFPF is expected to scale to high-dimensional problems [3].
