## **Abstract**

This paper outlines the methods and the estimation procedures that we have adopted for the calculation of the student scores in the database of the second TREE cohort (TREE2). In addition, we describe the calculation and the reporting of scale-specific statistics and quality measures given in the technical appendix and provide some clues for their interpretation. The appendix covers all questionnaire-based scales and item-based composites that have been administered in the baseline survey of TREE2 in 2016.

# Some practical guidelines for using the scales

For each scale, the technical appendix of this documentation provides a selection of relevant statistics and measures. Section 4 of the introductory text describes the type and calculation of the reported measures and gives some clues as to their interpretation. It is of course up to the data users to decide whether a scale shows the measurement properties required for their analysis.

The reported scale-specific measures focus primarily on reliability (in the sense of internal consistency) and measurement invariance across survey settings, modes and languages. What we do not address in this documentation is scale validity, as TREE mostly uses commonly accepted, well-established scales and validity is therefore not likely to be a major problem. In addition, the database offers researchers many opportunities to conduct external validations tailored to their specific analytical needs.

In some cases, several scales in the TREE2 scientific use file partly draw on one and the same items. The scales in question should therefore not be used simultaneously within the same multivariate model. This concerns some scales for which several versions exist (cf. section 2: scales sourrounded by dotted lines in Table 3) as well as other scales composed of main and subdimensions (cf. section 2, Table 4).

Regarding the use of student scores in the context of multivariate models, we refer the reader to the remarks on this issue in section 3.2.2. Some scores represent item composites rather than scale scores (cf. Table 5), which may, however, be used similarly. The variable names and labels of all items, student scores and composite variables in the technical appendix correspond with those in the scientific use file for the second TREE cohort (short variable names without wave-specific prefix).

When estimating the confirmatory factor models and calculating the student scores, we imputed all missing item information, provided that at least one item of a given scale had a valid rating (see section 3.1.1b for details).

## Introduction

This paper documents the questionnaire-based scales and item-based composites that have been collected on the occasion of the baseline survey administered to the second TREE cohort (TREE2) in 2016. First, the paper focuses on the methods and the estimation procedures that we have adopted for the calculation of the scale values published in the scientific use data files. Second, we describe the calculation of the scale-specific key figures and quality parameters (see appended tables) and provide some useful information for their interpretation.

The TREE2 baseline survey is composed of two surveys carried out at a short interval in spring/summer 2016. The first survey is a large-scale national assessment of mathematics skills administered to students who had reached the end of compulsory school (Assessment of the Attainment of Educational Standards, henceforth AES).1 Beyond the assessment itself, the AES survey programme included a comprehensive student background questionnaire that collected a wide range of student background characteristics presumed to influence maths skills development and/or educational and labour-market pathways in the further (post-compulsory) life course. The second survey, which we refer to as extension survey, was conducted shortly after the first one. Its main purpose was to complete some student background characteristics that had not been collected among all respondents of the first survey. In doing so, TREE was able to substantially extend the size of the TREE2 starting cohort (see section 1 for details).

All parts of the AES student questionnaire include numerous item-based measures designed to capture latent (i.e., not directly observable) respondent, family or context characteristics. Instrument selection was largely restricted to instruments validated by previous research in the relevant research fields (see section 2 for details).

The documentation of scales pertaining to the AES survey has been previously published along with the AES data in 2017 (Sacchi & Oesch, 2017).2 The present documentation covers the extended, more complex database of the TREE2 baseline survey, which also includes data from the extension survey described above. From a methodological point of view, this raises the issue of potential survey-mode and setting effects: The AES assessment was conducted in a uniform proctored classroom

The survey is part of an overarching assessment scheme implemented by the Swiss Conference of Cantonal Ministers of Education (EDK) to test basic skills in key subject areas at various stages of compulsory education. For details, see <a href="https://www.icer.unibe.ch">www.icer.unibe.ch</a> and <a href="https://wegk-schweiz.ch/">https://wegk-schweiz.ch/</a>).

See <u>forsbase.unil.ch/project/study-public-overview/16165/o/.</u>

setting supervised by carefully instructed test administrators; the extension survey, by contrast, took place in an unproctored individual setting outside of school. Furthermore, the latter employed two sequentially applied survey modes (web survey and paper-and-pencil questionnaire). With regard to scaling, this incongruence requires that we have to carefully check for measurement invariance across survey settings and modes. Consequently, this documentation includes a number of relevant invariance tests and parameters for all scales that are based on data from the extension survey.

Beyond psychometric scales stricto sensu, this documentation also includes a number of item sum scores based on two or more single items. However, we have not included scores of test results and other types of composite variables.<sup>3</sup>

For all scales and composites drawing exclusively on data of the AES assessment survey, we report the previously calculated parameters (Sacchi & Oesch 2017) in the technical appendix of this documentation. In doing so, we provide TREE2 data users with an overview of all scales and composite variables available in the TREE2 baseline survey in one single document (see particularly section 2). The introductory text describing the methods of calculation and estimation used and the parameters reported in the technical appendix largely corresponds to the 2017 AES documentation (ibid.).

For each of the scales, we report estimates (i.e., scores) of the individual scale values for all participating students. In addition, our documentation aims at enabling data users to assess the scales' quality and measurement invariance (cf. particularly the technical appendix). Last but not least, our documentation ought to allow scholars to replicate, if they wish to do so, the calculation of models, tests and scale parameters and compare them with alternative specifications.

In the following sections, we first specify some relevant aspects of the TREE2 baseline survey's design (1), the selection and adaptation of the scales (2) as well as the statistical modelling and calculation of the scale values (3). Finally, we specify how the scale-specific results, reliability and quality checks were calculated and give some information on how to interpret them (4).

-

As for the scales, the extension survey considerably enlarges the database on which these scores rely.

# 1 Survey Design and Database

The data of the AES survey were collected by means of a computer-based classroom survey among a random sample of approximately 22,000 students who were in their last year of lower secondary education (i.e., the 11th year<sup>4</sup> of compulsory schooling).<sup>5</sup> The survey included a comprehensive test of basic mathematical skills, along with a computer-assisted self-interview (CASI) of approximately 45 minutes. Among other things, the student questionnaire covered a broad selection of psychometric and other item-based measures, which are the subject of this documentation.

AES implemented a modular design with two different versions of the questionnaire, each of which were administered to a randomised split-half of the total sample. The main building block of one version was the mathematics module, which mainly covered student, teacher and classroom characteristics relevant to the successful acquisition of mathematical skills during compulsory education and to related didactical and pedagogical research. The core of the second version was a student background module co-designed by TREE to collect information on a broad range of resources of the surveyed students, their families and the schools they were attending at the moment of the survey. This module was specifically developed for the TREE2 panel survey in order to measure, as comprehensively as possible, the starting conditions deemed to be relevant for the respondents' further education and labour-market careers and their life courses in general. Both questionnaire versions included a common core ("general questions") that was completed by all students participating in AES. The common core incorporated items that are of general interest for the research objectives of both modules.

Due to the modular design of the AES questionnaire, a substantial part of the questionnaire pertaining to TREE-relevant starting conditions of post-compulsory pathways was administered to only half of the AES sample (see *Figure 1*). In order to complete the missing items for the respondents to the other half (termed "maths sample split" in Figure 1), TREE carried out an out-of-school "extension" survey immediately after the AES survey. With a few exceptions, the questionnaire used for this survey

<sup>&</sup>lt;sup>4</sup> Including two years of kindergarten.

<sup>&</sup>lt;sup>5</sup> See Verner and Helbling (2019) for a detailed description of the sampling and the population.

The random assignment of the students to one questionnaire version was to guarantee that - within each school and each test session - both versions were evenly distributed over the 13 different test booklets used for the preceding mathematics assessment. Hence, from the students' perspective, booklet and questionnaire version were two independent, fully exogenous conditions.

was equivalent to that of the background module in the AES survey, which was implemented in two "standalone" versions, either in the form of a web or a paper-and-pencil questionnaire. The minor adaptations of the questionnaire under these changed setting and mode conditions included slightly modifying the order of instruments and adding a newly designed scale that had not been administered in the AES survey.<sup>7</sup> Apart from that, the web implementation was largely indistinguishable from the CASI instrument used by the AES.<sup>8</sup>

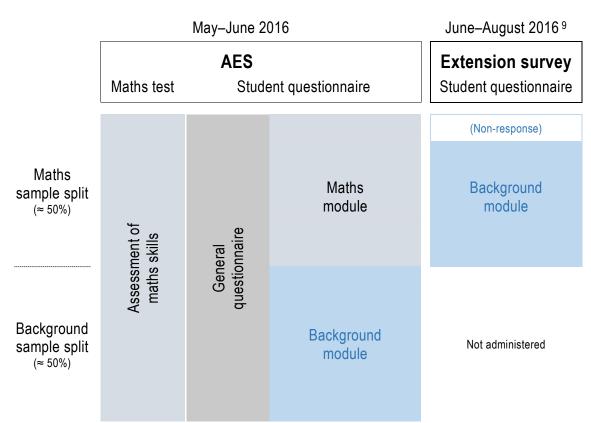

Figure 1: Design of the TREE2 baseline survey

In every canton, the extension survey was carried out as soon as the AES survey had been concluded in all sampled schools. The web survey was implemented as the primary mode. Students who did not participate in the web survey received the questionnaire's paper-and-pencil version by mail as a secondary mode. As both survey

Two additional elements were placed at the end of the questionnaire: a brief cognitive skills test (KFT 4-12 + R; Heller & Perleth, 2000) as well as an experimentally varied repeated measurement of parental education.

<sup>&</sup>lt;sup>8</sup> To maximise comparability with the AES CASI (and contrary to the web surveys in later TREE2 waves), the web mode was not adapted for smartphones (and respondents were asked to complete it on a computer).

<sup>&</sup>lt;sup>9</sup> The median lag between the AES and extension survey was 29 days. 98 % of respondents completed the questionnaire between June and August, with a few pencil-and-paper questionnaires being returned up to the end of October.

modes are self-administered, they are well suited for the partly sensitive questionnaire items included in the extension survey. With this mixed-mode design, the extension survey achieved a total response rate of almost 75% (73.3% if we consider only complete questionnaires; see also Table 1). Taking the relevant methodological literature into consideration, we do not expect significant mode effects (de Leeuw & Hox, 2011; de Leeuw, 2018; for proctored surveys see also Colosante et al., 2019).

As *Table 1* illustrates, the extension survey enabled us to substantially enlarge the available initial TREE2 sample base with a comprehensive measurement of relevant starting conditions. Among other things, this also allows for a more precise estimation of the scaling models and parameters that are at the centre of this documentation. <sup>10</sup> In light of the sample structure displayed in Table 1, it is important to address the issue of measurement invariance across the various survey settings and modes. That is why this documentation also provides statistical tests and quality measures that are relevant to this end (see section 4 and the technical appendix). The estimation of *setting effects* thereby draws exclusively on the CASI and the web survey, which rely on virtually interchangeable survey modes (i.e., it excludes the paper and pencil questionnaires, n = 15 608). And the estimation of *mode effects* draws exclusively on the extension survey (i.e. it excludes the classroom setting, n = 5 119). In doing so, we avoid the risk that the estimations of mode and setting effects are mutually confounded.

Table 1: Sample size and structure of the TREE2 baseline survey

	AES	Exter	Total	
Survey Setting:	Proctored classroom survey	Unproctored		
Survey Mode:	CASI	Web survey	P&P questionnaire	
(Sub-)sample size 2)	11 124 <sup>3)</sup>	4 484	635	16 243

1) Including 89 incomplete questionnaires (with data for some scales only), which are treated as nonresponses when it comes to response statistics and the published sample weights (see also FN 10). 2) The number of cases for particular scales will generally be lower due to non-imputable missing values. 3) Background sample split (cf. Figure 1).

\_

Regarding the scales partly relying on the extension survey, we draw on a customised sample weight tailored to the sample available for scaling purposes (cf. footer of Table 1). There are two types of non-neglible sample attrition, which exclusively affect the maths sample split (i. e. the unwillingness of AES respondents to provide their contact data for the TREE panel survey and non-participation in the extension survey). Given the high AES response rate of 93% (see Verner & Helbling, 2019: 39), the background split is therefore markedly less affected by attrition. The customised weight accounts for general and split-specific sources of attrition (see section 3.1.1a and FN 27 for further details).

These considerations do not affect the calculation of any of the scales administered in the general questionnaire and the AES maths module, as these scales do not rely on the extension survey. For calculations based on the general questionnaire, we can draw on data of the complete AES sample (approx. 22 000 students) and, for calculations based on the AES maths module, on the subsample to which the maths module was administered (approx. 11 000 students; cf. Figure 1). To ensure a statistically efficient estimate, the scaling models generally draw on the entire available sample base, including cases which, for various reasons, are not included in the scientific use files of the TREE2 dataset (Hupka-Brunner et al. 2021). 11

Table 2: Breakdown of estimation samples by survey languages

Scales implemented in  Available Estimation Sample <sup>2)</sup>	General questionnaire Full AES sample	Background module  Baseline survey 2)	Math module Math subsample
Survey Language:			
German	16 349	11 698	8 106
French	5 235	3 927	2 646
Italian	755	618	379

<sup>1)</sup> Number of cases for specific scales will in general be lower due to non-imputable missing values. 2) Cf. Table 1.

In a survey administered in several languages, we also have to be careful regarding measurement invariance across survey languages (in our case German, French and Italian), which concerns all scales administered. Basically, variance across languages can be the result of 'real' cultural or linguistic differences between language regions but also of inaccurate translations. That is why we report language-specific invariance tests and parameters (section 4 and appendix). As *Table 2* reveals, sample size substantially varies across survey languages.

Data users who wish to estimate or replicate scaling models drawing on the complete database may do so. As the data excluded from the published data files are highly confidential, however, this is possible only on the premises of the study's headquarter in Bern and using a specially protected computer workplace.

In the AES, the survey language is identical with the teaching language of the sampled schools. In the extension survey, respondents were able to choose the survey language. In a few cases, this led to the situation that the extension survey was not completed in the same (national) language as the AES survey.

# 2 Selection and Adaptation of Scales

The AES questionnaire incorporated a broad range of more than 90 item-based instruments from relevant research areas (for theoretical considerations regarding the selection of instruments, see Hupka-Brunner et al. [2015] and Hascher et al. [2015]). As a general rule, preference was given to well-established, cross-disciplinary validated instruments used in surveys both in Switzerland and abroad.

A first selection of instruments was thoroughly pretested in the year preceding the main survey (2015).<sup>13</sup> One important objective of the pretest was to assess measurement properties of the preliminary selection of questionnaire instruments and scales in the Swiss context. This included assessments of the dimensionality, reliability and the cross-language measurement invariance of the scales. Some of the scales had to be newly translated to make them available in all survey languages. In these cases, the pretest was used to check measurement invariance across language versions and to improve improper translations. Moreover, the pretest was used to clean up scales with dodgy items, to shorten others and, lastly, to narrow down and optimise the selection of instruments for the main survey. We shortened many scales to three or four items to ensure a comprehensive coverage of relevant concepts without unduly increasing response burden and interview duration.

Wherever possible, the original instruments were implemented without modification in order to preserve measurement properties of the selected scales and to maximise data comparability. However, given the multitude of aspects to be considered in questionnaire construction (Dillman, Smyth & Christian, 2014), slight adaptations of the original instruments often could not be avoided.<sup>14</sup>

The main objective of the pretest was to improve the assessment of mathematical skills, the design of the student questionnaire and the fieldwork for the main survey. The pretest sample was split evenly across the three test languages, German, French and Italian, and included more than 2 000 students from 70 schools.

The manifold methodological, empirical and substantive reasons for such adaptations include the following: At the methodological level, there was the need to adapt instruments that were originally developed for a different survey mode (de Leeuw, Hox & Dillman, 2008: 311f.) and to standardise the format of each type of question in order to reduce the response burden and improve comprehensibility (Dillman, Smyth & Christian, 2014: 210f.). Empirically, the pretest in some instances uncovered insufficient cross-language measurement invariance, which suggested the need to check and, in some cases, improve the translations of the instruments. Finally, there was the requirement to closely replicate some of the instruments from the first TREE cohort (TREE1).

The modifications of the original instruments can pertain to both the question format and wording of stimuli as well as to the response scales and sometimes even to the items. In most cases, however, they are minor so that a substantial impact on the measurement properties and comparability of the resulting scales seems unlikely. It should also be noted that, for similar reasons, many popular scales are far less standardised in survey practice than generally perceived. Moreover, in the case of several circulating scale versions, the original version of the scale is not necessarily the most appropriate.

Table 3 conveys a topically ordered overview of all scales and item-based instruments that were implemented in the AES main field. The 'Positive Attitude towards Life' scale was administered in the extension survey only. In a few cases, several scales partly rely on the same items. Consequently, they should not be introduced in one and the same multivariate model. Apart from scales involving main and sub-dimensions, the scales in question are framed by a dotted line in Table 3.

To enable comparative analyses between TREE1 and TREE2, the range of implemented instruments also includes some original scales used in the PISA 2000 survey, the baseline survey of the first TREE cohort (TREE1). For some of these scales (family wealth, social and cultural communication within the family), we implemented both the original version already used in PISA 2000 and an adapted version that was optimised for TREE2. The former is preferable for comparative analyses of both cohorts, the latter for analyses of the second cohort only.

In principle, all scales listed in Table 3 are one-dimensional, that is, they have been designed to measure *one* theoretical construct or latent dimension each. <sup>15</sup> However, some of the scales are composed of several sub-dimensions, each representing a facet of one overarching construct. As researchers may wish to distinguish between the sub-dimensions of these scales, the scientific use files of TREE2 also include student scores for each sub-dimension. The following table lists both the main and sub-dimensions of the scales in question.

Table 4 Scales with sub-dimensions

<sup>1)</sup> The short names of the student score variables in the TREE2 scientific use file are given in brackets. 2) In accordance with Huang et al. (2012) and Donnellan et al. (2016), this scale is clearly two-dimensional in the TREE2 baseline survey. 3) Sub-dimension labels according to Huang et al. (2012). 4) Corresponds to 'Cultactv' scale in PISA 2000/TREE1. 5) As this scale is not one-dimensional in the AES survey, we distinguish two (inductively optimised) sub-dimensions.

\_

One should note, however, that the one-dimensionality of the selected scales may be empirically controversial. For one scale, *Global Self-Esteem* (according to Rosenberg, 1979; 2014), we are aware that this is the case (see von Collani & Herzberg, 2003; Huang & Dong, 2012; Donnellan, Ackerman & Brecheen, 2016). With respect to this scale, we decided to provide the student scores for both the one-dimensional model and for the two sub-dimensions described in the literature. Hence, we treat this scale the same way as other scales with sub-dimensions and leave it up to the data users to decide on the appropriate scaling solution.

Some of the instruments described in this documentation are based on two items only, making it impossible to fit any scaling model to the data. Henceforward, we call scores derived from mostly short, item-based instruments *item-based composites* (for an overview see *Table 5*). <sup>16</sup> In case of the *'Family affluence scale'* in Table 5, the term «scale» is a misnomer as it represents de facto a sum score, i.e. an item-based composite (for details, see Hobca et al., 2017). <sup>17</sup>

Table 5: Item-based composites

Concept 1)			
Dimension	Variable name 2)	Number of items	
Big Five Inventory			
Extraversion	[big5_e_comp]	2	
Agreeableness	[big5_a_comp]	3 3)	
Conscientiousness	[big5_c_comp]	2	
Neuroticism	[big5_n_comp]	2	
Openness	[big5_o_comp]	2	
Locus of control			
Internal locus of control	[loci_comp]	2	
External locus of control	[loce_comp]	2	
Effort: learning (PISA2000) 4)	[effper_comp]	2	
Family values	[vafa_comp]	2	
Parents: reading interest	[joyreadp_comp]	2	
Emotional closeness to parents	[closep_comp]	2	
Family affluence scale (FASIII) FN17	[fasIII_comp]	6	

<sup>1)</sup> With the exception of 'Effort: learning' (general questionnaire, full sample), all composites belong to the background module. 2) The short variable names of the composite scores in the scientific use file are reported in brackets. 3) For the composite with one extra item, see Rammstedt and John (2007: 210). 4) This composite has been previously administered in the surveys of the first TREE cohort (TREE1).

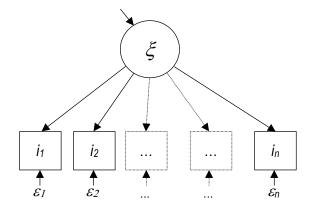

For item composits, student scores are calculated from imputed item ratings (cf. 3.1.1 b).

Note that this composite partly draws on the same items as the wealth scales in Table 3.

# 3 Statistical Modelling

As mentioned above, the scales in the AES questionnaire are item-based instruments intended to measure *one* theoretical construct each. Confirmatory factor analysis (CFA) is a common approach to the empirical estimation of latent (i.e., not directly observable) characteristics captured by such measurement instruments (see, e.g., Long, 1983; Schmitt, 2011). As our selection of scales is restricted to validated instruments that were designed to measure a common latent dimension, we limit ourselves to fitting a straightforward one-dimensional CFA model (see Figure 2 and Aichholzer, 2017: 80–84) to each scale-specific item set. The CFA model illustrated in *Figure 2* relies on n items ( $i_1$ ,  $i_2$ , ...,  $i_n$ ) with associated item-level measurement errors  $\varepsilon_n$ , which all measure the same latent dimension  $\xi$ . For scales with several subdimensions (see Table 4 above), a separate CFA model is fitted to each subdimension. <sup>18</sup>

Figure 2: One-dimensional confirmatory factor model

For every model estimated hereafter, selected model parameters, fit statistics and scale quality measures are reported in the technical appendix (p. 34ff.). This includes a test of one-dimensionality, various measures of internal scale consistency as well as tests and indices of measurement invariance across survey languages and, where appropriate, survey settings and modes. Throughout this documentation, our primary focus is the quality of the scales (and the corresponding student scores) rather than model fit. If the fit of the straightforward one-factor model turns out to be poor, we neither modify the model to improve fit nor do we test alternative (e.g., multi-

An alternative approach would be to fit second-order CFA models to each dimension (Aichholzer, 2017: 89f.).

dimensional) models. It is up to the data user to judge whether the one-dimensional CFA models are appropriate and whether the scales have the required properties.

#### 3.1 Estimation of the confirmatory factor models

In its standard form, structural equation modelling - including CFA as a special case - relies on a number of quite restrictive assumptions that are hardly ever met in practice. Basically, the observations should be independent, and the indicators should be measured on a continuous scale (interval-level measurement) and follow a multi-normal distribution (see, e.g., Hoyle, 2000). As regards the database of the AES and the TREE2 baseline survey, none of these assumptions holds: The two-stage sampling procedure implies that observations are clustered within schools (see Verner & Helbling, 2019) and hence are not independent. Moreover, measurement of the indicators is at ordinal (or binary) level as it mostly relies on Likert-type rating scales. And last but not least, the skewed univariate distributions of many ratings are hardly consistent with the required multivariate normality.

The methodological literature offers a wide range of suggestions on how to relax some of the assumptions of the standard SEM model and how to deal with ordinal, binary or skewed indicators and clustered observations (cf., e.g., Bryant & Jöreskog, 2016). In particular, the suggestions include two-stage estimation methods that exploit polychoric correlations and generalised structural equation models (GSEM) that are suited for short response scales and categorical indicators (Rhemtulla, Brosseau-Liard & Savalei, 2012; Bryant & Jöreskog, 2016). However, there is currently no well-established, generally accepted estimation approach tailored to both ordinal indicators that are not normally distributed and a complex sample with clustered observations.

We therefore follow the recommendations of Rhemtulla et al. (2012; similarly Harpe, 2015: 843) regarding the accurate estimation of CFA models on the basis of ordinal, Likert-type indicators. They suggest two different estimation strategies depending on the length of the rating scales. For item responses that rely on a rating scale with at least five points (i.e., ordered discrete response categories), they suggest a two-step estimation based on polychoric correlations. For item evaluations that rely on shorter rating scales with four or less points, a generalised structural equation model

15

Clustered observations may not only affect variance estimation and model fit but also bias the estimation of model parameters (i.e., factor loadings; cf. Stochl et al., 2016; Muthén & Satorra, 1995; Wu & Kwok, 2012).

(GSEM) is in order. Below, we describe these estimation strategies in more detail.<sup>20</sup> As our primary goal is to estimate accurate student scores, we also implement some sensitivity checks to assess the equivalence of student scores obtained via alternative model-estimation strategies (see section 3.2.1).

## 3.1.1 Two-step estimation based on polychoric inter-item correlations

The two-step approach starts with the estimation of a matrix of polychoric correlations between all items of a given scale (tetrachoric correlations, respectively, in the case of dichotomous items).<sup>21</sup> In the second step, maximum likelihood estimation is used to fit the one-dimensional CFA model from Figure 2 to the resulting correlation matrix.<sup>22</sup> The models are identified by setting the loading of the first item and the variance of the latent factor to one. The CFA models are also estimated separately for each of the three language subsamples. This allows for multi-group analysis designed to test and assess measurement invariance across the survey languages (see section 4 and, e.g., Steinmetz et al., 2008; Milfont & Fischer, 2015).

Below, we briefly describe how we deal with (a) the complex AES sample and (b) with missing item values in the context of the two-step estimation approach.

## (a) Complex sample design and survey weighting

The AES survey relies on a random sample of students that was disproportionally stratified by cantons and type of cantonal curriculum (Verner & Helbling, 2019).<sup>23</sup> Furthermore, the samples analysed here are also affected by sample attrition. An unbiased estimation of any population characteristic therefore requires the *application* of an appropriate survey weight to account for the disproportional sampling design as well as for unit nonresponse. This also pertains to the estimation of polychoric correlations or the parameters of the CFA models to be estimated (e.g., factor loadings).<sup>24</sup>

<sup>&</sup>lt;sup>20</sup> All calculations were performed using Stata version 15.0 (AES) and 16.1 (TREE2 baseline survey).

A polychoric correlation is defined as the maximum likelihood estimate of the correlation between two hypothetical, normally distributed continuous latent variables derived from two corresponding ordinal indicators. Estimations were calculated using the Stata package "polychoric" by Stas Kolenikov (from <a href="http://stas-kolenikov.net/stata">http://stas-kolenikov.net/stata</a>).

<sup>&</sup>lt;sup>22</sup> Maximum likelihood estimation has been found to be among the most appropriate estimation methods (together with ULS and DWLS; see Yang-Wallentin, Jöreskog & Luo, 2010) for analysing polychoric correlations derived from ordinal indicators.

Lower secondary schools in Switzerland are mostly "tracked", that is, students are enrolled in separate programmes with varying academic requirements.

Weighting would only be unnecessary in the case of a strict invariance of the postulated scaling model across subpopulations of any kind. If this strong assumption were met, the damage of unnecessarily applying survey

When estimating the polychoric correlations, we therefore use one out of three different survey weights, depending on whether a given scale is embedded in the background module, in the maths module or in the general questionnaire. For the scales from the latter two, we rely on the suitable AES weights. With regard to AES, module-specific analyses require particular weights, as the sampling design of the randomised sample split for the distinct questionnaire modules (according to Figure 1) differs with respect to the shape of disproportional cantonal stratification. On the basis of the module-specific AES weights, we have constructed an additional weight for the TREE2 baseline survey, which accounts not only for the AES sampling design and nonresponse but also for sample attrition in the extension survey.

As regards the two-step estimation approach, it should be noted that variance estimation does not account for the clustering of observations within schools implied in the two-stage sampling (see Verner & Helbling, 2019).

#### (b) Handling of missing item values

Missing item values are not a major problem affecting the scales in the AES survey. As usual in surveys, however, there is a small share of missing item values, owing mainly to item non-response. With the exceptions mentioned below, the share of cases with missing information on at least one item of the scale does not exceed 5%. For two out of three scales, the percentage is below 1%.

A considerably higher share of missing values results for half of the items of each of the four scales that measure different facets of 'specific self-efficacy' in mathematics. This is a direct consequence of the questionnaire design (and therefore not a matter

weights would be limited to inflating the variances of the estimates to some degree (Bollen, Tueller & Oberski, 2013). Given the huge AES sample, this would not be too disturbing.

We use the respective non-response adjusted weights from the AES scientific use file ('smp\_w\_nrastubw' for the scales of the general questionnaire and 'smp\_w\_qmath' for the scales of the maths module).

The reason is that the design of the two complementary sample splits has been optimised for two different purposes: The sample split drawn for the background module is designed to maximise statistical power at the national level, whereas the maths module split is optimised for separate analyses of cantons. In a nutshell, this was achieved by developing a disproportional subsampling scheme that further reinforces the general overrepresentation of small cantons among the sample split with the maths module and reduces it among the sample split with the background module. The weights for the sample splits then correspond to the general survey weight from the AES scientific use file ('smp\_w\_nrastubw') multiplied by the inverse of the within-canton subsampling fraction (see also Verner & Helbling, 2019).

For the baseline survey, we use an entropy-balancing weight (cf. Hainmueller, 2012; Hainmueller & Xu, 2013) that compensates for the AES disproportionate sampling design (incl. nonrespons adjustments) and, as far as the math-sample split is concerned, for the non-response related to willingness to be (re-)contacted and to participate in the extension survey (for details, see the TREE2 documentation on weighting: Sacchi, forth-coming). For the purpose of scaling, the e-balancing weight for the TREE2 baseline survey was re-estimated by taking into account the somewhat looser definition of survey participation employed throughout the scaling process (see Table 1 and the explanatory text).

of methodological concern<sup>28</sup>), as half of the items of each of these scales were incorporated into the general questionnaire and the other half into the maths module. This implies that the share of missing item information is close to zero for the general questionnaire, whereas it rises to around 50% for the items implemented in the maths module.

A relatively high share of missing values is also observed for two measures in which students evaluate the items on a rating scale that includes an explicit 'don't know' option. This pertains to the scale measuring 'perceived social network support' (*closupp\_fs*) and the two-item composite for parents reading interests (*joyreadp\_comp*). For both instruments, the share of missing information rises to 10.4 and 8.7%, respectively, when explicit don't-know answers are included.<sup>29</sup>

Finally, there are four instruments containing some items that could not be administered to a minor portion of the sample.<sup>30</sup> With one exception, the overall share of cases with at least one missing item does not exceed 5% in these instances.<sup>31</sup>

These special cases and exceptions notwithstanding, the fraction of missing items is low to very low for the bulk of the scales. Hence, the impact of missing item information is presumably limited.

We applied *multiple imputation* to cope with missing values when estimating the scaling models (Rubin, 1996; White, Royston & Wood, 2011). Basically, missing item information was imputed - scale-by-scale - on the basis of all valid items pertaining to the same scale. The imputed samples thus cover all cases with a valid response for at least one of the items of a given scale. Given the ordinal measurement level of the item ratings, we applied chained equations with an ordinal (or, in a few cases, binary) logit link to create samples with imputed values (Royston, 2011). Following the rules of thumb given in White et al. (2011: 388), we set the number of imputations to five.<sup>32</sup>

The randomised allocation of students to questionnaire modules ensures that the missing-at-random assumption (MAR), which is crucial for the imputation of missing values, is almost perfectly met here.

<sup>&</sup>lt;sup>29</sup> Missing item values owing to explicit don't-know answers and item non-response were imputed together.

Some items referring to specific relatives (e.g., the father) have not been administered when the students previously indicated that these relatives do not exist (this pertains to the instruments: Family Education Support, Parents Achievement Expectations, Parents Reading Interest and Emotional Closeness to Parents). The resulting missing values were treated the same way as other types of missing information. Although this is perhaps not an ideal solution in these cases, a substantial bias seems unlikely given the mostly very low number of cases to which this applies.

The exception is the 'Family Educational Support' scale (famedsup\_fs) for which the share of cases with at least one missing item amounts to 14.6%. This owes mainly to the item tapping sibling support, which was not administered among students who previously indicated that they have no siblings (see footnote 29).

The relatively low number of imputations seems appropriate for two additional reasons: First, we are primarily interested in unbiased point estimates of population parameters (e.g., factor loadings) and to a lesser degree in between-imputation and sampling variances. Second, some exploratory reproducibility checks, as

For each imputed dataset, we separately calculated a matrix of polychoric correlations and combined it to estimate the CFA models.<sup>33</sup>

For each scale-specific CFA model, we calculated statistics and indices describing factor structures, model-fit and scale properties (see section 4 and the technical appendix).

## 3.1.2 Generalised structural equation model for short response scales

If scales rely on item evaluations with short response scales of four or less points (including binary items), they were analysed using a generalised structural equation model (GSEM), as recommended in the literature (Rhemtulla, Brosseau-Liard & Savalei, 2012; Bryant & Jöreskog, 2016). Model parameter estimates were derived in one step directly from the microdata through numeric integration. To otherwood the two-step approach, this amounts to a full-information, true maximum likelihood method (Bryant & Jöreskog, 2016: 192). We henceforth adopted the GSEM version of a one-dimensional CFA model, mostly with an ordinal logit link to account for the ordinal measurement level of the item sets to be analysed.

#### (a) Accounting for the complex survey design

GSEM, as implemented in Stata, is able to account for complex sample designs. In particular, we used survey weights (as described in 3.1.1a) to obtain unbiased population estimates of the model parameters and applied cluster-robust variance estimation, which controls for the clustering of students within schools. Still, we assume that there is no substantive variation in the measurement model across schools (cf. Wu & Kwok, 2012).

#### (b) Handling of missing item values

GSEM estimation proceeds on an equation-by-equation basis. In the context of a simple one-dimensional CFA model, this amounts to an implicit treatment (i.e., imputation) of missing item values, as each item is represented by a separate equation.

suggested by White et al. (2011: 387), indicate that the polychoric correlations and other point estimates are highly stable for an even smaller number of imputations.

After applying Fisher's z-transformation, we simply average the correlation matrices and transform them back (see also footnote 31).

Integration mostly relies on mean-variance Gauss-Hermite quadrature with seven integration points (Stata-Corp, 2017: 562).

<sup>&</sup>lt;sup>35</sup> The ordinal logit link reduces to a simple logit link for the two scales that include binary items.

One drawback of the GSEM approach is that the calculation of most established statistics to describe model fit and scale properties is not straightforward. This is why we complemented the GSEM estimations for the item sets with short response scales by a separately estimated two-step model, as described in section 3.1. If the resulting factor structures and student scores do not substantially differ from those obtained via the GSEM approach, this may be taken as indirect evidence that the two-step approach works sufficiently well and its assumptions are met (in the appendix, we therefore also check for the equivalence of both types of student scores). Hence, the model and scale statistics taken from the two-step CFA model are likely to be valid approximations as well.

#### 3.2 Student scores

#### 3.2.1 Calculation and robustness of student scores

For instruments relying on item rating scales of 5 or more points, the student scores in the scientific use file (and the related descriptive statistics in the appendix) represent regression factor scores (see StataCorp, 2017: 582f. for details) from the two-step CFA models described in section 3.1.1. For scales based on item sets with short response scales (four or less categories), the student scores in the SUF are empirical Bayes means based on the GSEM models (ibid.: 566). The variable names assigned to the student scores in the scientific use file are composed of a prefix indicating the survey wave (e. g. 'to' in case of the baseline survey, 't2' for the 2<sup>nd</sup> follow-up wave), the root of the variable names of the involved items and the suffix '\_fs', which is used as a marker for student score variables. The corresponding suffix for the item composites from Table 5 is '\_comp'. The variable labels assigned to the student scores and item composites correspond to those contained in the scale-specific documentation in the appendix. For an unequivocal interpretation of the student scores in the TREE2 scientific use file, we recommend inspecting the factor loadings (see section 4). As a general rule, however, a high factor score will indicate that students score high on the latent dimension that is designated by the label of the student score variable.

For all scales, the model, scale and test statistics reported in the appendix rely on the two-step estimation approach described in section 3.1.1. This explicitly also applies to those instruments based on short response scales, where the student scores (and the related factor-score descriptives in the appendi

x) are derived from a GSEM model. We also check the calculation of student scores for robustness by reporting the shared variance of both types of student scores (from

SEM and GSEM) as measured by the coefficient of determination (CD) (see appendix: Equivalence of Scores from Two-Step Approach). If their shared variance is close to 100% (i.e., CD approaches 1), one may safely conclude, first, that the different modelling strategies have a negligible impact on student scores and, second, that it also seems reasonable to take the various fit and scale statistics obtained from two-step estimation as good approximations. As documented scale by scale in the appendix, the coefficient of determination is indeed close to 1 for most scales (> .94 for 42 out of 48 involved scales). There are six exceptions, however, in which the shared variance is substantially lower (between 60 and 90%), thus indicating that some of the additional assumptions needed for the two-step model have probably been violated. This pertains to the scales measuring absenteeism (truancy\_fs), family wealth as indicated by home possessions (both scale versions: wealth fs, wealth m fs), cultural activities including one of its subscales (cult\_fs, culthigh\_fs) and students' maths selfconcept (matcon\_fs). For these scales, the model and scale statistics reported in the appendix should be interpreted with great caution, if at all. Still, this does not indicate that the student scores estimated via the GSEM approach are biased in any way.

For an additional robustness check for the student scores, we re-estimated the confirmatory factor models in s single step directly from the student microdata by using the MLMV method (StataCorp, 2017: 574). This allows us to control for the complex survey design through weighting and cluster-robust estimation and, at the same time, to implement an alternative full-information maximum-likelihood approach to account for missing item values.

Let us again look at the shared variances between the student scores obtained via the MLMV method and those via the two-step approach described in section 3.1.1 (see appendix: Equivalence of Scores from Robust MLMV). <sup>36</sup> With the exception of the aforementioned wealth scale (both scale versions), the shared variances uniformly exceed 96% (i.e., CD > .96) for all of the 87 scales in this documentation. This can again be taken as indirect evidence that the additional assumptions of the two-step approach regarding multivariate normal distributions and the measurement level are mostly met and, hence, that the statistics and indices derived from it are valid. To sum up, the robustness checks imply that with the few exceptions mentioned above, student-score estimates are very robust across the three different estimation methods recommended for the type of data analysed here. <sup>37</sup>

<sup>&</sup>lt;sup>36</sup> A disadvantage of this method is that many statistics to judge model fit and scale qualities are unavailable.

<sup>&</sup>lt;sup>37</sup> This may be due to the fact that we analyse short, one-dimensional scales based on a large sample.

#### 3.2.2 Inclusion of student scores in multivariate statistical models

Instead of using the scale-specific student scores, there are often good reasons to embed scale-specific CFA models into a more comprehensive structural equation model of substantive interest and to fit them all together in one step (cf., e.g., Aichholzer, 2017). It should be noted, however, that simultaneous estimation of both the measurement and the substantive part of a structural equation model is not necessarily always the best choice (cf. Devlieger & Rosseel, 2017): When one analyses a subsample of limited size, for instance, robust estimation of more complex models may be impossible. Moreover, even when the sample is large, misspecification bias in one part of a complex model may spread to other parts when they are fitted in a single step. A two-step approach employing previously estimated factor scores to investigate the substantive part of the model may have methodological merits in this respect (ibid.). This approach also has methodological drawbacks, however, basically because it implicitly treats factor scores as error-free measures of the latent dimensions to be analysed.<sup>38</sup> Some of the resulting problems, possible biases and correction methods are discussed, for example, by Croon (2002), Lu and Thomas (2008), Jin et al. (2016), and Devlieger and Rossel (2017).

-

A random extraction of plausible values from the posterior distributions of the CFA models could be a quite obvious solution to this. However, contrary to skills assessment, this is an uncommon approach in the scaling of questionnaire items, possibly because of the reduced convenience this entails for data analysis.

# 4 Scale-specific reporting: content and interpretation

In this section, we outline the various statistics, indices and quality measures reported in the scale

. For each scale (or subscale; cf. Table 4), this report includes two pages with a variety of scale-specific statistics. Below, we take the scale that measures 'Parental pressure to achieve' as an example to illustrate the scope and interpretation of scale-specific results. Figure 3 displays the results for this scale as they appear in the appendix. If nothing else is mentioned, all reported results refer to the two-step estimation of the CFA model according to Figure 2. However, the student-scores descriptives refer to the scores obtained from the GSEM model, as the 'press' items are rated on a four-point scale (see section 3.2.1). The header of each scale-specific results section includes the name of the scale that is also used to label the related student-score variable in the scientific use file. Furthermore, the headers specify the sample basis on which the calculations for the respective scales draw (baseline survey, full AES sample or maths sample split).

The model and fit statistics reported include two likelihood-ratio tests as well as various common goodness-of-fit statistics, as discussed in the SEM literature (cf. Schreiber et al., 2006). The likelihood-ratio tests compare the current against the saturated model and the baseline model (basically postulating uncorrelated items), respectively. Ideally, we would expect a non-significant likelihood-ratio test of the current against the saturated model, which, for the reasons given above, is an unlikely result, however (see also van der Eijk & Rose, 2015). Moreover, for a well-fitting model, we expect the comparative fit index (CFI) and the Tucker-Lewis index (TLI) to approach 1, whereas the root mean square error of approximation (RMSEA) and the standardised root mean squared residual (SRMR) should be close to o. Conventional cut-off criteria indicating a good fit between the hypothesised model and the observed data are  $\geq$  .95 for CFI and TLI  $\leq$  .06 for RMSEA and  $\leq$  .08 for SRMR (see Hu & Bentler, 1999). Regarding Figure 3, one could tentatively conclude that the one-dimensional CFA model fits the achievement-pressure scale sufficiently well, with some reservations regarding RMSEA and TLI, however. Two fit measures designed to compare different models, Akaike's information criterion (AIC) and the Bayesian information criterion (BIC), are also reported. They may serve as a point of reference if data users wish to fit alternative scaling models to the data. Finally, the coefficient of determination (CD) may be considered as an alternative measure of composite reliability (in the sense of internal consistency; cf. Bollen, 1989: 220f.), to be interpreted similarly to the reliability measures below.

The output section to the right of the model-fit statistics presents the results on *scale reliability and dimensionality*. Among the various conceptualisations of measurement reliability discussed in the literature (e.g., Bollen, 1989), *internal scale consistency* is the most widely used in practical research. One important reason for this is certainly that internal consistency may be easily assessed without additional re-test or parallel measurements of the indicators. It should also be noted, however, that consistency measures avoid several conceptual drawbacks of possible alternatives (see Bollen,

1989: 209ff.). We report three alternative measures of internal scale consistency: Cronbach's Alpha is still the most widespread, although much criticised, consistency measure (ibid.: 217; Sijtsma, 2009; Revelle & Zinbarg, 2009; Trizano-Hermosilla & Alvarado, 2016). In a nutshell, it is widely recognised that alpha underestimates internal consistency if the indicators are ordinal or congeneric (i.e., not tau-equivalent) as is typical of most practical research situations. We nevertheless do report the classical version of alpha as it is part of most survey documentations and — if interpreted as a lower-bound estimate of internal scale consistency — may still be useful for comparative purposes.<sup>39</sup> In addition, we also report Ordinal Cronbach's Alpha, which is calculated the same way as classical alpha but from the matrix of polychoric instead of Pearson correlations (see Gadermann, Guhn & Zumbo, 2012: 5). This avoids downward bias owing to ordinal measurement. Finally, we also report McDonald's Omega, which is one of the most recommended measures of internal consistency. Omega is calculated on the basis of the factor loadings of the one-dimensional CFA model (according to formula 1 in Trizano-Hermosilla & Alvarado, 2016), which implies that it is adjusted for ordinal measurement. As omega is appropriate for congeneric indicators, it is probably the most adequate measure overall of internal scale consistency in our context (see also Yang & Green, 2015). Basically, values close to 1 indicate high internal consistency for all three measures. Looking at Figure 3, many researchers would probably interpret the identical ordinal alpha and omega values of .810 each as an indication of a 'good', consistent scale. It should be noted, however, that the widely used rules of thumb to determine whether internal scale consistency can be considered 'acceptable' or 'good' (usually values above .7 and .8, respectively) are not without problems. First, there exist various such rules of thumb with different critical thresholds. Second, and more importantly, such rules should not be applied blindly, as the acceptable level of internal consistency depends strongly on the type of analysis to be performed (Lance, Butts & Michels, 2006).40

A crucial assumption of the estimated CFA models is that the analysed item set captures only one latent construct. Therefore, we have also included a *test of the assumed one-dimensionality*. However, assessing dimensionality of Likert-type items is quite "risky business", as van der Eijk and Rose (2015) put it. We used explorative factor analysis of polychoric correlations followed by Horn's parallel analysis to assess the dimensionality of the item sets, which proves to be a comparatively well-performing

<sup>&</sup>lt;sup>39</sup> The Stata package "Alphawgt", which allows for weights, was used to calculate alpha (Jann, 2004).

There are some rather dubious rules of thumb that distinguish different levels of internal scale consistency (i.e., Cronbach's alpha). A popular variant is:  $\alpha < .5$ : unacceptable;  $.5 \le \alpha < .6$ : poor;  $.6 \le \alpha < .7$ : questionable;  $.7 \le \alpha < .8$ : acceptable;  $.8 \le \alpha < .9$ : good;  $.9 \le \alpha$ : excellent (cf. <a href="https://en.wikipedia.org/wiki/Internal consistency">https://en.wikipedia.org/wiki/Internal consistency</a>, accessed on June 23, 2020).

method (ibid.; Garrido, Abad & Ponsoda, 2013).<sup>41</sup> Basically, we applied an eigenvalue criterion that was corrected for random factors to account for sampling variance to determine the number of factors to be retained. In Figure 3, this approach gives us no reason to believe that the achievement-pressure scale is not one-dimensional, as only the eigenvalue of the first factor exceeds the critical value of zero. If we leave aside the scales composed of several sub-dimensions (cf. Table 4), the eigenvalues of the second factor are mostly below or only very slightly above zero for most of the scales in this documentation.<sup>42</sup> This being the case, we have no clear indication that the one-dimensionality assumption is violated.

The section below the model-fit statistics in Figure 3 documents the *standardised factor loadings* for each item, including standard errors and the confidence intervals. The item names correspond to those in the scientific use file (without the prefix-marker for the survey wave). High standardised loadings above, say, .6 or .7 indicate that neither measurement errors nor strong unique factors contribute excessively to the variance of the observed indicators. Almost all loadings reported in the appended scales reach this level. Occasionally, however, items show noticeably weaker loadings below .5 or even below .4, which some researchers may consider problematic. Eventually, the definition of an acceptable factor loading remains arbitrary and depends on the type of analysis, the number of scale items affected and the quality as well as the overall internal consistency of the scale (ibd.). As in other respects, we prefer to leave it to the data users to judge a particular scale's qualities.

To the right of the loadings, a number of *item descriptives* are reported, including the mean, the standard deviation, the range of the rating scale applied for item evaluation (min., max.) and the number of students with valid item data (see section 3.1.1b).

At the bottom of the first page of our scale-specific results, we report the *parameters* of the categorical GSEM model (cf. section 3.1.2) where it is estimated. Note that for this model, there are two types of item-specific parameters, namely, factor coefficients ('coef') that measure the effect of the latent variable on the indicator rating, and the estimated cut points ('cutx') on the logit distribution that separate the rating scale category 1 from category 2, category 2 from category 3 and so on. Hence, the number of estimated 'cut' parameters equals the number of ordered rating categories minus one. Remember that the GSEM model is used to generate student scores (see

<sup>&</sup>lt;sup>41</sup> The parallel analysis relies on the user-written "paran" package (Dinno, 2009).

<sup>&</sup>lt;sup>42</sup> Exception: the two wealth scales.

section 3.1) where students' item evaluations rely on short rating scales with four or less points (as documented by the item descriptives).

A second page of scale-specific results (see *Figure 4* below) is dedicated to tests and indices that assess *measurement invariance across survey languages* and, where appropriate, *across survey settings and modes*. This is an important facet of measurement quality, as student scores obviously should be comparable – i.e., measure the same concepts on a possibly invariant scale – across all kinds of measurement conditions and subsamples of the underlying student population. We focus on some of the most crucial tests suggested in the literature on the multi-group analysis of measurement invariance (e.g., Vandenberg & Lance, 2000; Milfont & Fischer, 2015) to assess cross-language measurement equivalence. On top of the second results page, we first report a chi-square test of the *equality of the item-covariance matrices* across survey

languages (German, French, Italian; cf. Table 2) and, when a scale relies on the TREE2 baseline survey (including the AES extension survey), across survey settings (class-room vs. unproctored) and survey modes (web survey vs. paper-and-pencil question-naire (PAP); cf. Table 1).<sup>43</sup> If the hypothesis of equal covariance matrices is not rejected, this would be a strong indication of measurement invariance, making any further tests obsolete (ibid.).

The chi-square tests assembled in the section below refer to the one-dimensional CFA model from section 3.1.1, which was re-estimated separately for each survey language and, where appropriate, for each survey setting and survey mode. Hence, the tests assume that a common latent dimension exists, and its invariance is investigated by means of multi-group analysis. The three tests are designed to distinguish different levels of measurement equivalence, as discussed in the literature (ibid.). The first test is for *metric measurement invariance*, that is, for equal factor loadings. A non-significant test indicates that there is no evidence against the postulated invariance of the factor loadings across the different survey conditions. The second test takes the model with invariant loadings as its baseline and tests it against an alternative model with invariant loadings and intercepts, which implies strong measurement invariance. Third and lastly, the latter model is tested against an alternative positing strict measurement invariance, which furthermore requires invariant error variances ( $\varepsilon_i$  in Figure 2). Given the nested structure of the compared models, strong invariance would require that the first two tests be not significant and strict invariance that all three tests be not significant. Although this is a rather standard approach to assess measurement equivalence, the reservations against chi-squarebased fit statistics discussed above in conjunction with model fit also extend to chisquare-based multi-group comparisons: Even if the cross-language variations in the model parameters are negligible, these tests will nearly always be significant given the mostly huge samples analysed here. That is to say, a level of measurement equivalence that would be adequate for nearly all practical research purposes would still not be enough to pass these tests. Against this background, it is rather surprising that, with regard to the achievement-pressure scale (see Figure 4), the hypothesis of a strong measurement invariance is rejected only for survey languages and settings but not for survey modes (where, however, the test samples are smaller; cf. Table 1).

Below the section with the chi-square-based invariance tests, we report two additional measures of factor equivalence, which will perhaps do better in meeting the

-

<sup>&</sup>lt;sup>43</sup> Technically, this was achieved by specifying a multi-group model without a latent dimension and then testing a completely unconstrained model against a constrained one with equal variances and inter-item covariances.

practical needs of many data analysts. The first one, *Tucker's congruence coefficient* (*TCC*), is a measure of *configural factor invariance* (calculated according to formula 1 in Lorenzo-Seva & ten Berge, 2006). Basically, it is a pattern-similarity measure that approaches 1 when the loading patterns observed in two groups or conditions are identical. We report the coefficient separately for each pair of survey languages as well as for the pairs of survey settings and survey modes, where appropriate. According to Lorenzo-Seva and ten Bergen (ibid.: 61), two factors may be considered as approximately equal for practical purposes if TCC exceeds .95. If we look at the scales documented in the appendix, this criterion is met for all pairwise comparisons across survey languages, survey settings and survey modes.

In addition, we also assess the degree of micro-level factor equivalence at the level of student scores. For this, we compare the student scores taken from an unconstrained model fitted separately for each language, setting or mode, respectively, with the student scores taken from a model for the entire sample on the assumption of strong measurement invariance (i.e., equal loadings and intercepts). If the differences between the former and latter are negligible across the analysed survey conditions, this is a strong indication that – from a practical point of view – the measurement can be regarded as sufficiently invariant. As a measure of micro-level agreement, we report - separately for each of the subsamples delineated by survey language, survey setting, and survey mode - the coefficient of determination (CD), which is calculated by regressing the student scores from the strong-invariance model on those from the unconstrained condition-specific models. Where the CD indicates that both scores share, say, 98% of their variance (i.e.,  $CD \ge .98$ ), deviations from the postulated strong invariance model may be regarded as negligible. All scales in the appendix satisfy this criterion with respect to mode and setting effects. With regard to survey languages, there are some differences in a limited number of cases, which mostly concern the Italian language. It should be noted, however, that a perfect agreement cannot always be expected even if the 'true' measurement model was absolutely invariant as the estimated student scores also include some random error. This is particularly true for the scores gained through the separate analysis of small subsamples, as is the case for the Italian questionnaire (n = 379 - 755, cf. Table 2) and the paperand-pencil mode (n = 635; cf. Table 1) of the extension survey (cf. Figure 1). Notably for these subsamples, the sampling errors in the factor loadings and hence also in the student scores are likely to be more substantial.<sup>44</sup> With this in mind, one could also

-

<sup>&</sup>lt;sup>44</sup> In combination with skewed item distributions, this is probably also the reason why a few of the models underlying the invariance tests did not converge so that the subsamples for the French and the Italian languages had to be collapsed for this purpose. We added an explanatory note at the end of the measurement-

accept a coefficient of determination of, say, .95 as an indication of a still fair level of measurement equivalence. Also with regard to language-specific invariance, almost all scales in the appendix satisfy this criterion.<sup>45</sup> In the case of the achievement-pressure scale in Figure 4, however, our results are unambiguous and do suggest a high degree of measurement equivalence across survey languages, settings and modes.

In the section following the measurement invariance tests and indices, we report the short variable names (*press\_fs* in Figure 3) of the student score variables in the scientific use file (from either ML-SEM or GSEM, depending on the length of the rating scales; see section 3.2.1).<sup>46</sup> The respective descriptive statistics refer to the sample base used for the calculation of the student scores (including cases not published in the scientific use files of the data release; cf. section 1).<sup>47</sup>

Either one or two measures of factor-score equivalence across different estimation methods are reported at the bottom of the second results page (see section 3.2.1), depending on the length of the rating scales applied for item evaluation. With regard to the achievement-pressure scale in Figure 4, they confirm a particularly high match of scores across all three estimation procedures.

equivalence section in the appendix, which is shaded in grey in these cases (e.g., the 'school reluctance' scale).

Exceptions to the rule: the Italian versions of 'vawe', 'ictintr', 'cogselfb' and 'cultposs'. In the case of 'cultposs', this applies to the French version as well.

The full variable names include an additional prefix to distinguish TREE2 survey waves (e.g. "t2" for the second follow-up survey).

<sup>&</sup>lt;sup>47</sup> Relevant sample sizes are reported under "Factor score descriptives: Obs.". We also report the share of cases with imputed item values.
