DETERMINATION OF IMPURITIES IN ICE-CORES
FROM THE JUNGFRAU-JOCH
BY NEUTRON ACTIVATION ANALYSIS

(Received November 15, 1976)

An ice-core of 4 m length was drilled at the Jungfraujoch. It was divided into 18 sections and analyzed for solid and dissolved material by neutron activation analysis using nondestructive counting as well as chemical group separations. The solid material was identified as stone dust. Part of the dissolved material seems to originate from dissolved limestone, whereas many elements can not be accounted for by this hypothesis and must be due to atmospheric fallout.

Introduction

Studies of the composition of aerosols and of atmospheric precipitations have proved a valuable tool to determine the purity of our atmosphere, and these studies are rapidly increasing in number. However, nearly all of these investigations bear only on the present day situation. In order to find any long term changes, it would be highly desirable to compare the present composition with values of the past. Unfortunately reliable analytical data exist only for the last decade or so. However it was postulated that a record of past atmospheric precipitations going back many hundreds of years is kept in ice and is therefore available for analysis with present day methods. Thus MUROZUMI et al.¹ analyzed ice samples almost 3000 years old from the Antarctic continent and from Greenland and found a sharp rise in the content of Pb after 1940. Generally analysis of ice samples from Antarctica was much stimulated by the international expeditions to this continent.

Contrary to north and south polar ice sheets, the glaciers of the temperate zone have not been extensively surveyed as to the purity of the ice. This may be due partly to the fact that the situation in temperate zone glaciers is complicated by possible melting processes in summer and by the proximity of dust emitting bare rock formations. It was the aim of the present work to furnish analytical data for

a temperate zone glacier which would determine whether information similar to that in polar ice sheets is also contained in such glaciers. The analyses covered a wide range of elements including heavy metals and those likely to be of marine and of dust origin. All analyses were done by neutron activation.

Experimental

Collection of samples

Samples were taken in April 1974 at the Jungfraujoch (Switzerland) at an altitude of 3470 m with a teflon coated SIPRE core auger. The ice core has a length of 4 m and a diameter of 7.5 cm. It was packed into a polyethylene hose and kept frozen at -18°C until the time of analysis. A length of 4 m would correspond to an undisturbed accumulation of 3 years. However subsequent analysis for ^3H revealed that the ice was probably older than 30 years and that there was severe intrusion of recent water by melting processes.²

Preparation of samples

The method chosen for the preparation of the samples were influenced by several considerations:

(1) It is known that ice from glaciers contains inclusions of solid particles. Although some workers do not take care to remove solid material from ice^{1,3} or from river water,⁴ we thought this indispensable. Since we wanted to determine short lived activities such as ^{28}Al , ^{52}V , ^{49}Ca and ^{38}Cl , this separation had to be made prior to the irradiation. This in turn meant that irradiation of the entire ice core, although desirable from the point of view of blanks, was not feasible.

(2) The concentration of the elements in the alpine ice were not known even as to their order of magnitude. They were estimated to be between the concentration of polar ice (Na 20 ppb, total solids 0.1 mg/kg)¹ and of English rain (Na 1340 ppb, total solids ≥ 4 mg/kg).⁵ It was anticipated that Na would be one of the most abundant elements and that most other elements would be in the sub-ppb region. This in turn implies points 3 to 5.

(3) The blank problem will be severe.

(4) In order to achieve the necessary sensitivity, sample size must be several 100 g of ice.

(5) The anticipated dominance of ^{24}Na over other medium lived activities necessitates some chemical separations after the irradiation.

Taking these points into consideration, the following working scheme for the preparation of the samples for irradiation was adhered to:

(1) Core sections of 10–20 cm length with a weight of 400 to 800 g were melted in an all quartz apparatus. The first 50 ml were discarded in an effort to remove any surface contamination of the ice that might have come from the drilling operation.

(2) The remainder of the water was filtered in the same all quartz apparatus through an $8\ \mu$ and a $0.1\ \mu$ membran filter (Sartorius SM 11 301 and SM 11 309, diameter 25 mm) in order to remove any solid material.

(3) To the filtered water 200 mg of very pure NH_4NO_3 was added and the water was shell frozen in a 4 l round bottom pyrex flask. The NH_4NO_3 was added to make possible the subsequent handling of the very small amounts (~ 1 mg) of the freeze-dried material.

(4) Two samples at a time were freeze-dried over a period of 36 hrs to a constant pressure of $7 \cdot 10^{-6}$ bar.

(5) The flasks were removed to an airtight glove box and the solid contents transferred to especially clean polyethylene irradiation containers and then weighed.

Special experiments with radioactive and with activable tracers were done to check if this procedure allows the complete recovery of material originally dissolved in the water. The following ions (in amounts between 0.1 and $10\ \mu\text{g}$) were found to give recoveries between 0.95 and 1 from 500 ml of water: Al, K, Ca, Sc, Mn, Co, Zn, Cd, Sb, Eu. This is in good agreement with other investigations.⁶ The two elements which showed low recoveries (0.5 ± 0.1) were Cl and Br. This fact must be due to the slight acidity of our samples (which had a pH of 5.5 in correspondence to the pH of the ice samples), since the recovery of Br from neutral solutions is reported to be 1 and the recovery of I from solutions of pH 1.5 to be (0.7 ± 0.2).⁶

Activation, chemical separation and measurement

The freeze-dried residue was irradiated in the SAPHIR reactor for 5, 12 and 510 minutes, corresponding to integrated neutron doses of $2 \cdot 10^{15}$, $3 \cdot 10^{16}$ and $2 \cdot 10^{17}\ \text{n} \cdot \text{cm}^{-2} \cdot \text{sec}^{-1}$. The first two irradiations were made with a pneumatic transfer system that had a transport time of 6 sec.⁷ Activity measurements were done by Ge(Li) γ -ray spectroscopy without chemical separations after the first two irradiations and with chemical separations after the third irradiation; in the latter case a well-type Ge(Li)-detector was used for enhanced efficiency.

All spectra were stored on magnetic tape and analyzed on a CDC 6600/6700-computer. The program^{8,9} locates statistically significant peaks, fits a modified Gaussian function to the peaks and calculates the mass of the target elements by comparison to a standard. The standards were made of NH_4NO_3 to which the elements of interest were added, and thus were identical to the samples as far as

Table 1
Irradiation and measuring conditions

Irradia- tion time	Decay	Measuring	Nuclide	Half-life	γ -line used, keV	Determination limit, μg	
5 m	1.5 m	2.5 m	^{28}Al	2.25 m	1779	$3 \cdot 10^{-2}$	No chemical separation
			^{52}V	3.71 m	1434	$1 \cdot 10^{-3}$

matrix and geometry are concerned. The data pertinent to activation and measurement are given in Table 1; detection limits given are those calculated for an ice sample of mean composition.

The chemical separation after the third irradiation is mainly based on the quantitative and selective extraction of groups of elements with different metal-dithiocarbamates as reagents.¹⁰⁻¹² The sample is dissolved in 5N HClO_4 with the addition of 50 μg of the appropriate carriers and heated until it reached a temperature of 200 °C. The solution is then brought to pH 1 and subjected to several extraction steps (Table 2). Every element considered is extracted to better than 98% in a single extraction with the exception of Zn. Zn is distributed between fraction 2

Table 2
Sequence of extractions

Extraction number	Condition of aqueous phase	Reagent ^a	Concentration	Extraction time	Elements observed regularly in ice samples ^b
1	HClO ₄ , pH 1	Bi(DDC) ₃	2 · 10 ⁻³ M in CHCl ₃	5 m	Cu
2	HClO ₄ , pH 1	Zn(DDC) ₂	2 · 10 ⁻³ M in CHCl ₃	2 m	Cd, Mo; Zn (30%)
3	reduced with KI and ascorbic acid. 1N in HCl	Zn(DDC) ₂	2 · 10 ⁻³ M in CHCl ₃	2 m	As, Sb
4	citrate buffer, pH 5	NH ₄ DDC	2 · 10 ⁻³ M in CHCl ₃	5 m	Fe, Co; Zn (70%)
5	pH 2	HDEHP	25% in toluene	5 m	Sc, La, Sm, Eu

^aDDC: diethyldithiocarbamate, HDEHP: bis (2-ethylhexyl) orthophosphoric acid.

^bUnless otherwise noted, extraction for a given element is >98%.

(ca. 30%) and fraction 4 (ca. 70%); its total recovery however is 0.98 ± 0.01 . The organic extracts have a volume of 30 ml and are evaporated to 3 ml before counting. It was ascertained that this evaporation step entails no loss of activity. Four samples and two standards can be handled by one man in 5 hrs.

The chemical separation outlined above, while necessitating some work, had the following beneficial effects on the analysis:

(1) the decontamination from ²⁴Na and ⁸²Br was better than 10⁴, thus eliminating difficulties with large Compton backgrounds and allowing measurement very soon after activation.

(2) Splitting up the different activities into several groups diminished the possibility that one dominant activity will greatly reduce the sensitivity for all other activities; noteworthy in this respect is the great amount of ⁶⁴Cu which is removed by the first extraction.

(3) The assignment of a γ -line to a specific nuclide can be made without any further checks (such as additional lines or decay curves), since most ambiguities can be ruled out by considering the chemical properties.

Blanks and reproducibility

The blank values for the carrier material NH₄NO₃, for the filters and for the irradiation container are given in Table 3. When comparing these values to the values found in ice, which are also given in Table 3, it can be seen that the highest blanks are in general contributed by the filters. Separate experiments were therefore done to determine how much is washed out from the filters by filtering

Table 3
Blank values and experimental reproducibility

Element	$\mu\text{g per } 200 \text{ mg NH}_4\text{NO}_3$	$\mu\text{g per filter } 0.1 \mu$	$\mu\text{g per filter } 8 \mu$	$\mu\text{g per irradiation container}$	$\mu\text{g/kg ice, mean}$	Relative standard deviation, artificial solutions, %
Al	$3 \cdot 10^{-2}$	$2 \cdot 10^{-1}$	$6 \cdot 10^{-2}$	$1 \cdot 10^{-1}$	4	15

Sc	$<7 \cdot 10^{-6}$	$7 \cdot 10^{-6}$	$<4 \cdot 10^{-6}$		$6 \cdot 10^{-4}$	10
Sm	$<6 \cdot 10^{-7}$	$3 \cdot 10^{-6}$	$2 \cdot 10^{-6}$		$9 \cdot 10^{-4}$	10
La	$<8 \cdot 10^{-6}$	$2 \cdot 10^{-5}$	$1 \cdot 10^{-5}$		$4 \cdot 10^{-3}$	10
Eu	$<7 \cdot 10^{-7}$	$5 \cdot 10^{-7}$	$<3 \cdot 10^{-7}$		$3 \cdot 10^{-4}$	10

500 ml of water. It was found that $(3.8 \pm 1.8) \mu\text{g Na}$, $(2 \pm 0.5) \mu\text{g Ca}$ and no Al, Cl or Mn is washed out. Thus the contribution by the filters to the blank is substantial for Na and negligible for Ca, Al, Cl and Mn. All results have been corrected for these blank contributions.

The reproducibility of the determination were checked by analyzing several aliquots (usually more than 6) of artificial aqueous solutions that contained the elements to be determined in concentrations equal to the mean concentration found in the ice samples. These results are also given in Table 3. The observed relative standard deviation is in most cases larger than is to be expected from counting statistics, from the variation in the recovery of the freeze-drying process and from the recovery of the chemical separations. The experimental coefficient of variation must therefore contain some contribution from blank problems.

Results

A full discussion of the results exceeds the scope of this communication and will appear elsewhere.¹³ However a few of the findings will be discussed here.

Analysis of the material on the filters

All filters have been analyzed non-destructively by neutron activation after filtration of the melted ice. The results (filter blanks subtracted) are given in Table 4. It is immediately clear that the filters do contain substantial amounts of material (column b). This was no surprise but deserves stressing in view of the fact that

Table 4
Analysis of the material on the filters

(a)	(b)	(c)	(d)
Element	μg on both filters (mean of 13 sections)	$\frac{\mu\text{g on filters}}{\mu\text{g in filtered water}}$	$\frac{8 \mu \text{ filter}}{\text{both filters}}$
Al	$1.6 \cdot 10^1$	10	0.9
V	$2.2 \cdot 10^{-2}$	3.1	0.8
Mn	$1.6 \cdot 10^{-1}$	0.16	0.8
K	6.2	0.12	0.8
Cl	4.6	0.03	0.5
Ca	$\lesssim 5.4$	$\lesssim 0.06$	$\gtrsim 0.6$
Na	1.2	0.04	1.0

Table 5
Mean concentration ($\mu\text{g/kg}$) in ice and rain

Element	Ice Jungfrauoch present work	Ice Mont Blanc ³	Ice Greenland ¹⁴	Rain England ⁵

Eu	$(2.5 \pm 1.4) \cdot 10^{-4}$			

many previous investigators who performed ice, snow or water analyses explicitly omitted any filtration or centrifugation step;^{1,3,4} it also casts some doubt on the validity of the practice of acidifying samples before filtration. When the amount retained on the filters is compared to the amount in solution (column c), the elements are seen to clearly fall into three categories: Al and V are much more abundant on the filters than in solution; Mn and K are predominantly in solution, and Cl, Na and Ca are almost exclusively in solution. It is further seen that the majority of the solid material is retained on the 8 μm filter (column d). Examination of the filters by scanning electron microprobe revealed particles of uniform appearance with Ca as the major element and conglomerate particles with lines due to Al and Si. It is sought that these particles are stone dust blown by wind from limestone and from granite rock formations, both of which are present within 500 m from the drilling place. This conclusion is supported by the ratios of Al, V, Mn and K on the filters, which are roughly the ones expected for a granite.

Analysis of the filtered melt water

The mean results of 18 sections from the ice core are given in Table 5 together with typical values of rain and of ice from Greenland and from Mont Blanc. Pending further statistical evaluation, only the following points can be noted here:

— The standard deviation of the sections relative to their mean is much larger than the standard deviation found for artificial solutions of comparable concentrations. However many elements are positively intercorrelated, and a similar anomalous fluctuation is noted for the ^3H -content at the same location.² It is thus thought that the section to section variation is real; the reason for this remains open.

— Most concentration found at Jungfraujoch are intermediate between Greenland ice and English rain.

— Na and Cl seem to be largely of maritime origin. The Cl/Na ratio is 3 ± 1 , which is somewhat larger than the 1.8 valid for seawater. Values as high as 14 have been found in Antarctica.³

— Ca seems to derive from soil dust. While the values for Cl, Na, K and Mn in the ice from Col du Midi in the Mont Blanc³ roughly coincide with our values from Jungfraujoch, we do find 30 times more Ca in the latter place. This could be attributed to the presence of limestone formations within 500 m from the Jungfraujoch, while there are no such formations within 10 km from Col du Midi. The fact that most of the Ca is found in the meltwater must be due to its dissolution by carbonic acid.

— The Br/Cl ratio is 6 times larger than the value expected from seawater alone. Br could possibly be of anthropogenic origin.
