## ABSTRACT

Radon is a radioactive noble gas found in Earth's crust. It accumulates in buildings, and accounts for approximately half the ionizing radiation dose received by humans. The skin is considerably exposed to ionizing radiation from radon. We aimed to evaluate the association between residential radon exposure and melanoma and squamous cell carcinoma incidence.

The study included 1.3 million adults (20 years and older) from the Swiss National Cohort who were residents of the cantons of Vaud, Neuchâtel, Valais, Geneva, Fribourg, and Ticino at the study baseline (December 04, 2000). Cases of primary tumours of skin (melanoma and squamous cell carcinoma) were identified using data from cantonal cancer registries. Long-term residential radon and ambient solar ultraviolet radiation exposures were assigned to each individual's address at baseline. Cox proportional hazard models with age as time scale, adjusted for canton, socioeconomic position, demographic data available in the census, and outdoor occupation were applied. Total and age specific effects were calculated, in the full population and in non-movers, and potential effect modifiers were tested.

In total 4937 incident cases of melanoma occurred during an average 8.9 years of follow-up. Across all ages, no increased risk of malignant melanoma or squamous cell carcinoma incidence in relation to residential radon was found. An association was only observed for melanoma incidence in the youngest age group of 20–29 year olds (1.68 [95% CI: 1.29, 2.19] 100 Bq/m<sup>3</sup> radon). This association was mainly in women, and in those with low socio-economic position.

Residential radon exposure might be a relevant risk factor for melanoma, especially for young adults. However, the results must be interpreted with caution as this finding is based on a relatively small number of melanoma cases. Accumulation of radon is preventable, and measures to reduce exposure and communicate the risks remain important to convey to the public.

## 1. Introduction

Radon-222 is a naturally occurring radioactive noble gas and a product of the decay processes of uranium found in the Earth's crust. It

has a half-life of 3.8 days and readily diffuses into its surroundings, becoming widespread and releasing radioactive particles in the process (Avrorin et al., 1982; National Research Council, 1988). Buildings are susceptible to radon accumulation through the release of gas from

building materials, diffusion from water systems and drains, and through cracks in the foundations (Nazaroff, 1992). The primary contributors to indoor radon concentration are local geology (granite and metamorphic rocks) and soil, with the rate of transfer into buildings influenced by various factors such as ventilation, temperature differential, and building material permeability (Ramola et al., 2011; Ruano-Ravina and Wakeford, 2020). Radon has been estimated to contribute 40% of the overall annual radiation exposure in Switzerland (Roth et al., 1996).

The International Agency for Research on Cancer classifies radon as a Group 1 carcinogen based on the evidence from early epidemiological and experimental studies on lung and respiratory tract tumours (IARC. *Man-made mineral fibres radon*, 1988). A causal link was established between radon exposure and lung cancer based on the strong evidence from occupational, case-control, general population cohorts, occupational and experimental animal model studies (Kang et al., 2019; Sethi et al., 2012; Darby et al., 2005; WHO, 2009; Ruano-Ravina et al., 2023). The lung and respiratory tract are the organs that are the most affected by radon exposure through inhalation, with dosimetry indicating that the skin receives the next highest dose (Kendall and Smith, 2002). Radon and short-lived radon daughters (polonium, bismuth, and lead) emit alpha and beta particles (Darby et al., 2001). These alpha and beta emitting decay products can attach to aerosol particles via electrostatic interactions and deposit on the skin surface (Eatough and Henshaw, 1992). The emitted particles can travel through the skin tissue and deposit their energy (Eatough and Henshaw, 1995). Stem cells are located in the basal layer of the epidermis and within range of both alpha and beta particle penetration. Alpha particles, that penetrate less deep, can still irradiate the basal layer especially in thinner parts of the skin, such as face, forearms and frontal trunk (on average 40, 50 and 70  $\mu\text{m}$ ) (Konishi and Yoshizawa, 1985; Sandby-Mø et al., 2003). Alpha particles can also induce a negative effect to cells that are not directly irradiated via cell signalling from irradiated neighbour cells, which is called bystander effect (Brenner and Sachs, 2002). For these reasons, radon and its progeny can potentially irradiate the skin, reaching the basal layer of the epidermis to induce skin cancer (Eatough, 1997; Charles, 2007a). The annual radiation dose to the skin from radon exposure in indoor air at a level of 200  $\text{Bq}/\text{m}^3$  has been estimated to be 25 mSv (Kendall and Smith, 2002). It has further been estimated that around 0.7% (0.5–5%) of skin cancer incidence could be attributed to the radon exposure at 20  $\text{Bq}/\text{m}^3$  level (Charles, 2007b). Lastly, a recent experimental study on mice indicated that radon exposure could affect the structure of the skin, induce damage and result in dysregulation of gene expression (Mo et al., 2022).

Melanoma (MM) is a type of skin cancer that develops from melanocytes in the basal layer of the epidermis and has a much higher mortality rate than non-melanoma skin cancers (NMSC), specifically squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) (Linares et al., 2015). However, the relationship between residential radon exposure and skin cancers is not well understood, with conflicting results among the few available studies. One of the first epidemiological studies investigating the relationship between radon and melanoma incidence was conducted among Czech uranium miners and reported a non-significant increased risk (Kulich et al., 2011). Two ecological studies conducted in southwest England found higher incidence rates for SCC and NMSC in areas with higher radon levels (Wheeler et al., 2012, 2013). A Danish study, with modelled radon concentration at residential addresses, found an increased risk of BCC incidence, but not other types of skin cancer (Brauner et al., 2015). A cohort study in the Galicia region of Spain found a statistically significant risk of NMSC incidence for people living in homes with measured radon levels greater than 50  $\text{Bq}/\text{m}^3$  compared to those with lower levels (Barbosa-Lorenzo et al., 2016). The complex nature of the relationship between radon exposure and skin cancer incidence may vary depending on the cancer subtype, the level and duration of exposure, and individual susceptibility.

Prior research on the relationship between radon and skin cancer in

Switzerland focused on mortality. The first study found that radon exposure increased the risk of death from MM and all skin cancers when the erythemal-weighted UV dose was taken into account (Vienneau et al., 2017). With longer follow-up and updated residential radon and ambient UV exposure models, a subsequent study showed a smaller increased risks. The hazard ratios (HRs) and 95% confidence intervals (CIs) for 100  $\text{Bq}/\text{m}^3$  radon increase were 1.10 (95% CI: 0.99, 1.23), 1.06 (95% CI: 0.75, 1.49) and 1.09 (95% CI: 0.99, 1.21) for MM, NMSC and all skin cancers combined, respectively (Boz et al., 2022).

Given that deaths from melanoma represent only about 18% of incident cases, (Sung et al., 2021) studies on melanoma incidence can provide more sensitive risk estimates to complement previous mortality research. We aimed to investigate the association between radon exposure and melanoma incidence using robust, nation-wide individual level radon and UV exposures.

## 2. Methods

### 2.1. Swiss National Cohort & cancer registries

This study is based on a cohort constructed by combining data from selected cantonal cancer registries and the Swiss National Cohort (SNC). The SNC longitudinal research platform links nation-wide censuses to mortality and emigration records (Bopp et al., 2009). As it is census-based, involvement is mandatory and the SNC captures an estimated 98.6% of the Swiss population in 2000 (Swiss Federal Statistical Office, 2004).

The incidence cases (detailed below) were obtained from each cantonal cancer registry (CR) separately for the following six southwestern Swiss cantons: Vaud (VD), Neuchâtel (NE), Valais (VS), Geneva (GE), Fribourg (FR), and Ticino (TI). These CRs were selected due to available linked records to the SNC and relatively high radon levels within these cantons. Permissions to use the data were obtained through the National Institute for Cancer Epidemiology and Registration (NICER) and each individual cancer registry. These records were transferred to the Center for Primary Care and Public Health (Unisanté) to consolidate into a single, consistent database with all skin cancer cases. Through a prior project by the Institute of Social and Preventive Medicine at the University of Bern, cancer registry data were probabilistically linked to the December 4, 2000 census records within the SNC (Plys et al., 2022). Thus, this study leverages this existing CR-to-SNC linkage to acquire the full population within each canton and the necessary variables including residential coordinates, mortality and emigration records, demographic information, and a socio-economic position index (Swiss-SEP). (Panczak et al., 2012).

The malignant melanoma and squamous cell cancer (C43 and C44, respectively) cases were determined by using International Classification of Disease for Oncology, Third edition (ICD-O-3), codes (Report, 2005). Using morphology codes defining the histologic composition of cancer cells within the primary cancer, we distinguished cutaneous malignant melanoma (8720–8790), and squamous cell carcinoma (8050–8084, 8560–8574). No *in situ* cases were included. Incident melanoma was used as the main outcome.

### 2.2. Study population & follow-up

All adults aged 20 years and older and living in the cantons of Vaud, Neuchâtel, Valais, Geneva, Fribourg, and Ticino were included. Given the one-time linkage with the SNC, cases within each CR were included from December 4, 2000 (as the earliest possible date) to December 31, 2011. The exact date range for each CR differed depending on both the availability of the one-time linkage to the SNC and the registration processes of the registry (Vaud, Neuchâtel: 2000 to 2011; Valais: 2000 to 2010; Geneva: 2000 to 2009; Fribourg: 2006 to 2011; Ticino: 2000 to 2008) (Fig. S1). Most CRs were registering skin cancers at the time of the 2000 census, except for Fribourg which began on January 1, 2006.

Hence, people living in Fribourg were included in the analyses with delayed entry.

### 2.3. Exposure assessments

We utilized the same exposure assessments for both residential radon and ambient UV exposures as in the previous nationwide study on melanoma mortality in Switzerland (Boz et al., 2022). Based on their residential coordinates at baseline, modelled indoor radon (in Bq/m<sup>3</sup>) and ambient UV (in mW/m<sup>2</sup>) exposures were assigned to each participant. The residential radon exposure model used here was developed using a random forest approach and is fully described elsewhere (Vienneau et al., 2021). The model was based on ~80,000 measurements collected from 1994 to 2017 and stored in the Swiss radon database by the Federal Office for Public Health (FOPH) (Barazza et al., 2017). The measurement dataset was divided into 5 random subsets, for a 5-fold modelling strategy to evaluate robustness (i.e. 5 models, each with 80% data used for model development and the remaining 20% for validation). The average of the 5 models was used to obtain the final predicted residential radon levels. A range of geographical and building information were used as predictors, specifically: season of measurement and measurement epoch (before or after 2005), lithology, texture of the soil, groundwater quality and depth, terrestrial radiation, distance to the nearest geological fault, altitude, type of the building, construction period, floor of the household dwelling, canton of the residence and degree of urban of the area. The five-fold modelling strategy showed the models to be robust, though the performance metrics indicated uncertainty (R<sup>2</sup> 0.31; Spearman's rank correlation 0.51; root-mean-squared-error 0.74 ln Bq/m<sup>3</sup>). Further diagnostics also suggested some exposure misclassification, as the model tended to

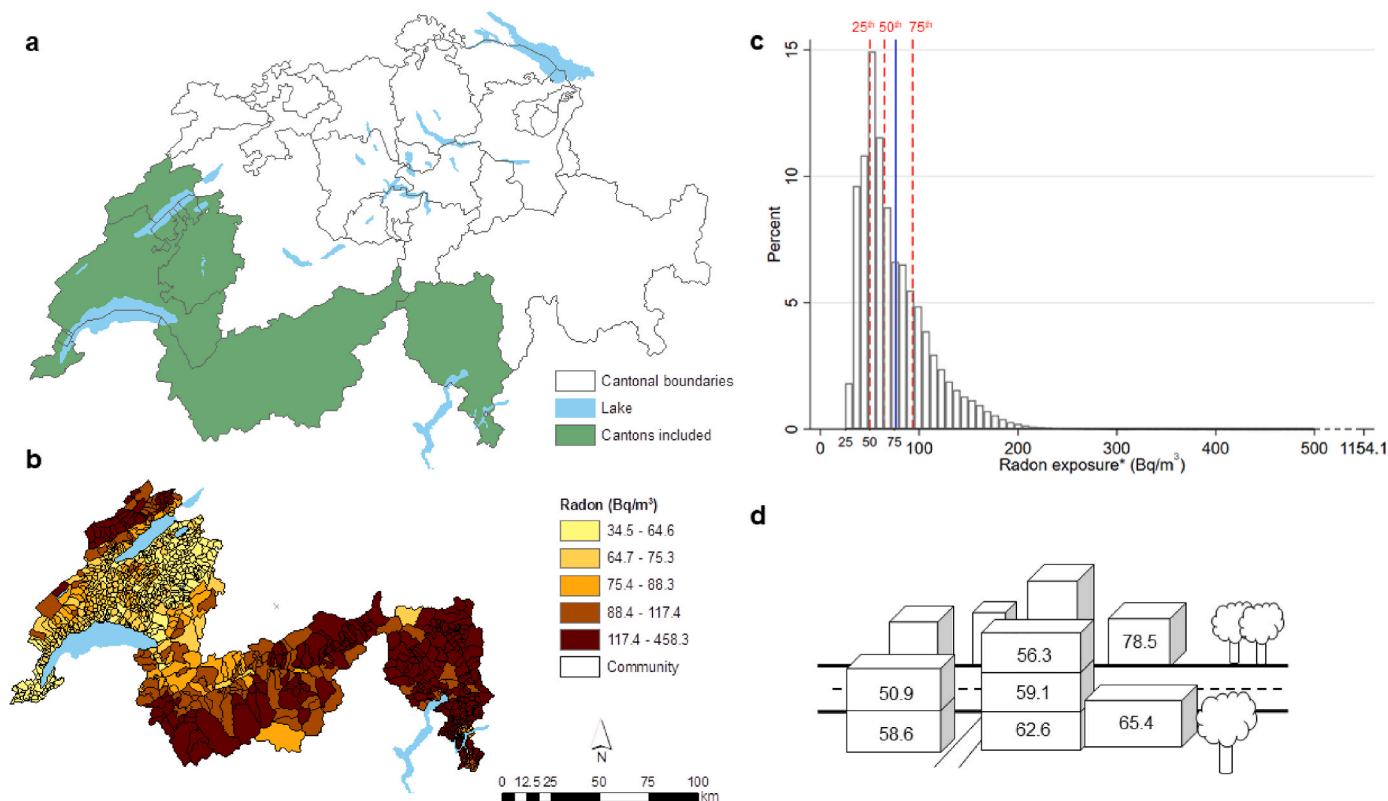

underestimate residential radon concentrations at lower radon levels and overestimate at higher radon levels (Vienneau et al., 2021). The residential radon exposure distributions, including community level averages for illustrative purposes only, are shown in Fig. 1.

The monthly UV climatology data covering the period from 2004 until 2016 were provided by MeteoSwiss with a spatial resolution of 1 × 1 km (Harris et al., 2021; Vuilleumier et al., 2021). These monthly data were used to calculate an annual average of the whole period and assigned to the coordinates of the participants at baseline. Additionally, a job-exposure matrix was linked to ISCO-88 codes within SNC to determine whether an individual had a job with the potential for UV exposure from the sun (also referred to as “outdoor occupation”) (Gué et al., 2001).

### 2.4. Statistical methods

The Cox proportional hazard model was used with age as a time scale (Kleinbaum and Klein, 2012). All participants were considered at risk as of the date of the census (December 04, 2001), except for those in Fribourg where January 01, 2006 was used (cancer registry in Fribourg was created in 2005 and considered complete from 2006 onwards). Follow up ended on the last day of 2011 for participants living in canton Vaud, Neuchâtel, and Fribourg, 2010 for Valais, 2009 for Geneva; and 2008 for Ticino. Participants were followed-up until that date or until one of the following events: the first occurrence of malignant melanoma, death, emigration from the country, or other loss to follow-up. The date of diagnosis was only available as a month and year, thus each event was considered to have happened on the 15th day of the month.

The Cox model included residential radon exposure (Vienneau et al., 2021) and ambient UV exposure (Vuilleumier et al., 2021) both as

**Fig. 1.** (a) Switzerland showing the cantonal boundaries and six included cantons. (b) Residential (household level) radon exposure averaged at community level within six cantons. Quintiles were used to categorize the radon levels. (c) Exposure distribution of residential radon for the study population at baseline. Red vertical lines represent the percentiles. Blue vertical line shows the mean value equal to 76.3 Bq/m<sup>3</sup>. \*Radon exposures above 500 Bq/m<sup>3</sup> were omitted to obtain a clear visualization. (d) Schematic of the residential radon levels by household, showing differences by household floor in the same building and between neighbouring buildings.

continuous variables. It was adjusted for: canton as a fixed effect to account for differences in background incidence of melanoma; population demographics and administrative variations between cantonal CRs; education attainment (compulsory school, upper secondary, tertiary, unknown) because of known differences in care-seeking (Buster et al., 2012); marital status (single, married, widowed, divorced), to reflect differences in lifestyle and culture; and Swiss-SEP (Panczak et al., 2012) (continuous). The model was stratified by sex (men, women), mother tongue (German, French, Italian, other), and outdoor occupation (binary: indoor job not exposed to UV in work place, not employed or retired vs. working outdoors) in order to allow different baseline hazards. The proportional hazard assumptions were tested visually using log-log plots and Kaplan-Meier survival curves (Schoenfeld, 1980).

First, estimates for the overall population were derived. Biological considerations (Kamiya et al., 2015) and the previous study for Switzerland on skin cancer mortality (Boz et al., 2022) indicated that radon effect may vary with age. We thus split the data into the following age groups: 20–29, 30–44, 45–59, 60–74, 75 and older, and an interaction term was introduced between radon exposure and age group to obtain age-specific estimates. Hazard ratios and 95% confidence intervals were reported per 100 Bq/m<sup>3</sup> radon (the annual average residential radon concentration reference level set by the WHO (WHO, 2009) to obtain effect estimates comparable to previous similar studies (Brauner et al., 2015; Vienneau et al., 2017; Boz et al., 2022)). A sensitivity analysis was carried out on the sub-set of non-movers identified as those who lived at the same address in both the 1990 and 2000 census (thus 10 years prior to earliest start date). Effect modification by sex, socio-economic position (converted to binary using the arithmetic mean of the continuous variable), and outdoor occupation were also investigated by comparing the models with and without an interaction term with radon exposure; the reported HRs and p-values from the likelihood ratio test were calculated by age group.

The main outcome definition was incidence of primary malignant melanoma. We also conducted secondary analyses using SCC incidence as outcome. Different to the main analysis, the secondary analysis excluded Ticino due to lack of records for SCC, and the Fribourg follow-up was until end of 2012 (Fig. S1). BCC was not investigated as a secondary outcome because it is less consistently registered and incomplete in most cancer registries.

Individuals in cancer registries may have multiple entries if diagnosed with more than one type of skin cancer (SCC or BCC, in addition to melanoma). Because UV exposure is the major risk factor for all types of skin cancers, and behaviours that lead to UV exposure may change after diagnosis or treatment, we censored upon diagnosis of other skin cancers (SCC or BCC) in a sensitivity analysis.

### 3. Results

The study population comprised 1,575,923 adults living in the six studied cantons, representing 21.7 % of the Swiss population in 2000 (Fig. S2). We excluded 113,530 (7.7%) because of failed linkage to the consecutive census in 2010. We further excluded 49,225 (3.1%) because of missing geographical coordinates for their home location, 49,433 (3.1%) because they were living in non-residential buildings (such as hospices and retirement homes), and 816 (0.1%) individuals because of missing SEP index. The remaining 1,362,919 participants were included in the analysis with total of 12,120,549 person years of follow-up (average 8.9 years) and 4937 primary malignant melanoma cases.

The average age of the full study population and melanoma cases were 49.1 and 55.7 years, respectively. Almost half (48.7%) were non-movers prior to baseline, 53.8% of whom were women and on average older compared to the full study population. On average, individuals in the cohort were married, French speaking, and had completed upper secondary education. Approximately 4% of the cohort were working outdoors with potential for UV exposure (Table 1). The percentages of population within age groups were 14.1, 34.4, 27.3, 18.1 and 9.0 for age

**Table 1**

Population characteristics of the full cohort and non-movers, including for malignant melanoma cases.

| Characteristics                   | Study population |                       | Sub-set population      |                       |

<sup>a</sup> MM cases: Primary invasive cutaneous melanomas (ICD-O-3: C43, 8720–8790). No *in situ* cases.

<sup>b</sup> Non-movers: Same residential location at 1990 and 2000 censuses.

<sup>c</sup> Percentages calculated for the row.

groups 20–29, 30–44, 45–59, 60–74, 75 and older, respectively. The proportion of cases was highest in 60–75 years old group (1578 [32.0%]) and lowest in youngest age category (110 [2.2%]) (Table S1). The mean radon exposure was 76.4 Bq/m<sup>3</sup> with a standard deviation of 40.6 Bq/m<sup>3</sup>, approximately 20% of individuals were living in homes with residential radon exposure exceeding the established guideline limit of 100 Bq/m<sup>3</sup> by World Health Organization (Fig. S3). Radon and ambient UV exposures were not correlated ( $r = 0.08$ ).

We observed no association between radon exposure and melanoma across all age groups, with a hazard ratio of 1.03 (95% CIs: 0.94, 1.13) per 100 Bq/m<sup>3</sup>. A risk increase was only found in the youngest age group (1.68 [1.29, 2.19] per 100 Bq/m<sup>3</sup>). Similar results were observed when the analysis was restricted to non-movers (Table 2).

None of the variables we tested modified the effect of radon exposure on melanoma incidence for all ages combined (Table 3). The noted association in the youngest age group seemed to be mainly in women and in those with lower socio-economic position, with no association in their counter parts.

In the secondary analysis, we found no association between radon exposure and SCC incidence (Table S2). The sensitivity analysis where we also censored on the first diagnosis of SCC or BCC, if occurring before a melanoma diagnosis, did not change the main results (Table S3 vs. Table 2).

#### 4. Discussion

In this cohort study including cantons in Switzerland prone to radon, no association was found between residential radon exposure and incidence of cutaneous malignant melanoma or squamous cell carcinoma. Even the analysis restricted to non-movers, where exposure misclassification is expected to be reduced, showed no association. The only increased risk for melanoma incidence in relation to radon exposure was in the youngest adults (aged 20–29), and based on a relatively small number of cases (2.2% of all cases) thus should be interpreted with caution. The association in young adults remained when restricting the analysis to the non-movers. In addition to the modifying effect of age, the association between radon exposure and melanoma incidence was stronger among women and in individuals with lower socio-economic status.

Previous analyses in the entire population in Switzerland on the relationship between residential radon and melanoma mortality found positive associations (Vienneau et al., 2017; Boz et al., 2022). One possible explanation for the lack of association with incidence might be that while the people living in the Alpine regions have higher radon exposure they also could have lower access to health care due to infrastructure and be less inclined towards regular screening. Thus, they may be diagnosed in the later stages of prognosis compared to those living in urban settings, inducing survival bias in the previous study (or a diagnosis bias in the present study). With no further possibility to untangle the all confounding factors affecting the complex relationship between exposure and the outcomes, we cannot exclude these biases. On the other hand, the observed stronger effects of radon on melanoma incidence for younger adults and women is consistent with the previous

**Table 2**

Association between residential radon exposure and melanoma incidence among the full cohort and non-movers, by age.

|            | Full cohort |                           | Non-movers <sup>a</sup> |                           |

Notes: Models used age as time scale, included radon exposure, and adjusted for ambient UV exposure, sex, canton, socio-economic position, education, marital status, mother tongue, and outdoor occupation.

Effect modification was evaluated using an interaction term between radon exposure and each potential effect modifier. For the age group analyses, three-way interaction terms were used between radon exposure, age group and the potential effect modifier.

Hazard ratios (95% confidence intervals) are expressed per 100 Bq/m<sup>3</sup> radon increase.

<sup>a</sup> Based on Swiss-SEP (Panczak et al., 2012): Low and high means the neighbourhood socioeconomic index value is lower than 60 and equal or higher than 60, respectively. 60 is the mean value of the cohort.

<sup>b</sup> No includes those with indoor jobs and those not in paid employment.

<sup>c</sup> Not applicable because of no observed cases in that group.

studies on melanoma mortality, suggesting the link between radon exposure and melanoma risk should not be dismissed. For squamous cell carcinoma, however, we found no increased risk with increase in residential radon levels. This is contrary to a previous study on skin cancer incidence and ionizing radiation dose conducted within atomic bomb survivors that reported statistically significant excess relative risks for BCC and SCC but not for MM (Sugiyama et al., 2014). Within Mayak nuclear facility workers who were chronically exposed to ionizing radiation, a higher risk for BCC but not SCC was found (Azizova et al., 2021). Together these finding might indicate the exposure to ionizing radiation is more related to risk of BCC, a notion that is supported by the findings of the Danish Diet, Cancer and Health cohort study (Brauner et al., 2015). Unfortunately BCC incidence as an outcome could not be considered in our analysis.

That we only saw signs of a relationship for melanoma in the young adults could relate to ionizing radiation having more effect early in life (Tong and Hei, 2020). Previous evidence supports that the carcinogenic effect of ionizing radiation is age dependent (Crosfill et al., 1959; Ritz et al., 1999; Smoll et al., 2016), but also that risks related to age at exposure can differ depending on the cancer type (Preston et al., 2007). Excess risks seem to decrease with age at exposure for stomach and thyroid cancers, while the risk of breast and lung cancers gradually increases at older ages (Shuryak et al., 2011). Regarding skin cancer, a study among atomic bomb survivors indicated a one year of decrease in age at exposure related to an 11% increase in the risk of BCC. The results, however, were inconclusive for melanoma due to a low number of cases (Sugiyama et al., 2014). A similar pattern was also found in a study on BCC in relation to radiation therapy. The relative risk was highest among people who received radiation therapy during childhood, and the

risk gradually decreased with the age at exposure (Karagas et al., 1996). Considering that the risk from ionizing radiation does not diminish for decades for many solid cancers including skin (Shore, 2001), exposure at very young ages extends the period to develop carcinogenesis and increases the opportunity to detect an adverse outcome. This fits with our observation of a slightly stronger association among young adults who were non-movers, with exposure at baseline also reflecting residential exposure during childhood with less uncertainty. It may be that ionizing radiation from residential radon has more effect on the skin when exposed early in life because the skin of infants is thinner and gradually increase from birth to adulthood (Saitoh et al., 2015). The thickness of skin reaches its maximum around 25 and 35 years of age, then slowly loses its elasticity and moisture content while remaining the same thickness until the very old age (Shuster et al., 1975).

Evidence suggests that the effect of ionizing radiation is different on males and females (Narendran et al., 2019). The report published by the National Research Council in 2006 investigating the biological effect of ionizing radiation (BEIR VII, phase 2) showed that women are more likely to develop cancer or die from cancer compared to men when exposed to the same amount of radiation (National Research Council, 2006). The susceptibility, however, can vary greatly from no known differences by sex for certain solid cancers to large differences for other cancer types. For example, a pooled cohort study among nuclear workers occupationally exposed to ionizing radiation in the United States observed no significant effect modification by sex for non-smoking related radiogenic cancer (bone, skin, brain, breast, central nervous system, thyroid) (Schubauer-Berigan et al., 2015). For malignant skin cancers, a Russian cohort study among nuclear facility workers exposed to gamma-rays also did not observe any modification of excess relative risk by sex (Azizova et al., 2018). We can only speculate that higher risk of melanoma with regard to residential radon exposure observed in our study, and primarily in the youngest women, might be due to women having thinner skin or spending more time indoor at home than men (Dao and Kazin, 2007).

Socio-economic status is also associated with melanoma incidence, with higher incidence reported in educated high income populations (Jiang et al., 2015). Similarly, we observed statistically significant positive coefficients for continuous socio-economic status and higher coefficients in those with higher attained education (upper secondary and tertiary) compared to those in a lower category (data not shown). The possible reasons could relate to behaviours such that people with higher socioeconomic status are more likely to travel to destinations with higher UV exposure, such as mountains or seaside holidays, compared to people with lower socioeconomic status (Clarke et al., 2010), and they are more likely to examine their skin regularly and undergo screenings (Jiang et al., 2015). We saw no risk, however, in the high SEP population group in the effect modification analysis. It may be that any small increase in risk has been masked by the substantially higher risk from recreational UV exposure (Erdei and Torres, 2010). Instead the noted higher risk of melanoma incidence in relation to radon exposure in the lower SEP group, especially in the younger adults, might be explained by lower quality housing and lack of access to or the cost of remedial efforts. The national level radon remediation survey for Switzerland revealed that the major reasons for not taking action against high residential radon levels are the high cost of the required renovations and that radon is not considered a health risk (Barazza et al., 2017), the latter which may also differ according to SEP.

The strength of this analysis is that it is a large prospective cohort study, with an average of 9 years of follow-up. Residential radon and ambient UV exposures were assigned to every individual's addresses at baseline. The exposure assessment for radon was from a model to predict residential (i.e. household) levels, built on a very large number of measurements across the country, allowing for detailed spatial modelling including by floor of dwelling. Moreover, the registration of incident melanoma cases is systematic and can be considered as complete for all the CRs used in this study.

Still it must be acknowledged that exposure was modelled for, not measured in, every home. We also did not have data on behaviours that may influence radon exposure, such as the amount of time spent indoors and ventilation practices at home. Exposure misclassification due to these factors cannot be avoided and is a limitation of this study. Future studies may be better suited to address these issues. We also could not include adults across the whole of Switzerland, because of unavailability of previously linked cancer registries to SNC. However, the study covered most cantons with known high spatial variability of radon levels. Another potential limitation is the relatively coarse model used to adjust for long-term average ambient UV exposure, with a  $1 \times 1$  km which represents an ecological exposure. Further, high intensity intermittent UV exposures, especially in childhood, are known to be more important than average ambient UV exposures for melanoma risk (Erdei and Torres, 2010). Unfortunately, we did not have information about personal UV exposure history and sun-related protection behaviours, which can markedly affect the dose from ambient UV. Finally, it should be noted that the only positive association was based on a small number of cases within young adults. Furthermore, for some individuals, only considering residential radon may not have captured the total radon exposure given that indoor exposure may also occur in occupational settings (Whicker and McNaughton, 2009). Future studies could also consider other designs and exposure assessment methods, such as individual long-term radon measurements possibly considering time activity, to capture both residential and occupational exposures.

## 5. Conclusion

The overall results provide little evidence for an association between residential radon exposure and melanoma incidence. Nevertheless, residential radon exposure might be a potential risk factor in the early stages of adulthood, in particular for women and those with lower socio-economic position. Studies involving other cantonal cancer registries within Switzerland, or elsewhere, with longer follow-up would help clarify the relationship between radon exposure and skin cancer risk. From a public health perspective, and based on the stronger evidence for lung cancer, radon exposure remains an important risk factor for the health of the general population. Therefore, prevention and mitigation of radon gas in dwellings with high radon levels should continue to be promoted by governmental organizations and international agencies.
