**Aims** Cardiac myopathies are the second leading cause of death in patients with Duchenne and Becker muscular dystrophy, the two most common and severe forms of a disabling striated muscle disease. Although the genetic defect has been identified as mutations of the dystrophin gene, very little is known about the molecular and cellular events leading to progressive cardiac muscle damage. Dystrophin is a protein linking the cytoskeleton to a complex of transmembrane proteins that interact with the extracellular matrix. The fragility of the cell membrane resulting from the lack of dystrophin is thought to cause an excessive susceptibility to mechanical stress. Here, we examined cellular mechanisms linking the initial membrane damage to the dysfunction of dystrophic heart.

**Methods and results** Cardiac ventricular myocytes were enzymatically isolated from 5- to 9-month-old dystrophic *mdx* and wild-type (WT) mice. Cells were exposed to mechanical stress, applied as osmotic shock. Stress-induced cytosolic and mitochondrial  $\text{Ca}^{2+}$  signals, production of reactive oxygen species (ROS), and mitochondrial membrane potential were monitored with confocal microscopy and fluorescent indicators. Pharmacological tools were used to scavenge ROS and to identify their possible sources. Osmotic shock triggered excessive cytosolic  $\text{Ca}^{2+}$  signals, often lasting for several minutes, in 82% of *mdx* cells. In contrast, only 47% of the WT cardiomyocytes responded with transient and moderate intracellular  $\text{Ca}^{2+}$  signals. On average, the reaction was 6-fold larger in *mdx* cells. Removal of extracellular  $\text{Ca}^{2+}$  abolished these responses, implicating  $\text{Ca}^{2+}$  influx as a trigger for abnormal  $\text{Ca}^{2+}$  signalling. Our further experiments revealed that osmotic stress in *mdx* cells produced an increase in ROS production and mitochondrial  $\text{Ca}^{2+}$  overload. The latter was followed by collapse of the mitochondrial membrane potential, an early sign of cell death.

**Conclusion** Overall, our findings reveal that excessive intracellular  $\text{Ca}^{2+}$  signals and ROS generation link the initial sarcolemmal injury to mitochondrial dysfunctions. The latter possibly contribute to the loss of functional cardiac myocytes and heart failure in dystrophy. Understanding the sequence of events of dystrophic cell damage and the deleterious amplification systems involved, including several positive feed-back loops, may allow for a rational development of novel therapeutic strategies.

## 1. Introduction

Dystrophinopathies result from mutations of the dystrophin gene (reviewed in Ervasti and Campbell<sup>1</sup>). Dystrophin is a 427 kDa protein linking the cytoskeleton to a complex of transmembrane proteins, which interact with the extracellular matrix. Duchenne and Becker muscular dystrophy (DMD and BMD) are the two most common and severe forms and are characterized by progressive and disabling muscle weakness (one case per 3500 boys). Cardiac manifestations are present in essentially all patients by 20 years of

age. The most common abnormality is dilated cardiomyopathy. Around 20% of the patients succumb from the cardiac manifestations. Clinically, the disease initially shows ECG abnormalities. Later, echocardiographic examinations reveal ventricular wall motion abnormalities in regions of fibrosis. With spreading of fibrosis, ventricular dysfunction and arrhythmias occur, ultimately leading to heart failure and sudden death.<sup>2</sup> With improving medical care for the skeletal muscle weakness, the cardiac disease becomes more and more limiting for the survival of the patients.

In the skeletal muscle field, there is a significant body of data describing the cellular pathophysiological events (for review see Allen *et al.*<sup>3</sup>). It is generally believed that the

dystrophin deficiency leads to exaggerated sarcolemmal fragility. Abnormal  $\text{Ca}^{2+}$  influx and intracellular  $\text{Ca}^{2+}$  homeostasis after mechanical stress have been implicated in progressive death of dystrophic skeletal muscle fibres.<sup>4,5</sup> The *mdx* mouse is a well-established model for skeletal muscle dystrophy, and it also develops a cardiac phenotype with age that is similar to the alterations observed in humans during dystrophic cardiomyopathy.<sup>6</sup> It is suggested that in skeletal muscle  $\text{Ca}^{2+}$  entry could occur via voltage-independent pathways,<sup>3</sup> such as 'leak' channels,<sup>7</sup> stretch-activated channels (SAC),<sup>8</sup> or store operated channels (SOC).<sup>9</sup> The molecular identity of these channels is not yet fully clear, but some of them are thought to contain TRP channel subunits.<sup>3</sup> In addition, there are findings suggesting that the vulnerability of *mdx* muscle leads to microruptures which may also allow excessive  $\text{Ca}^{2+}$  influx.<sup>10</sup> Despite all these identified possible pathways for  $\text{Ca}^{2+}$  entry, the main question still remains open: what is the sequence of cellular events that initiate  $\text{Ca}^{2+}$  influx and which are the positive feed-back loops that amplify this influx and lead to  $\text{Ca}^{2+}$  overload and cell death?

Identical questions apply to the cardiac phenotype, but much fewer studies were carried out to understand cellular mechanisms leading to cardiac pathology. However, the clinical findings described above and some experimental studies on the organ level also indicate an abnormal sensitivity of cardiomyocytes to mechanical stress, for example, after aortic banding<sup>11</sup> or prolonged exposure to  $\beta$ -adrenergic stimulation to induce arterial hypertension.<sup>12</sup> In addition, histological examination revealed replacement of muscle with connective tissue and the presence of apoptotic and necrotic myocytes, also in cardiac muscle.<sup>13,14</sup> Thus, cell death most likely underlies the development of fibrosis and progressive deterioration of both tissues.

A functional study found a high stress sensitivity of isolated *mdx* cardiomyocytes and that the cell damage could be suppressed by the membrane protective detergent Poloxamer P188.<sup>15</sup> In addition, a report suggested SAC to contribute to the abnormal  $\text{Ca}^{2+}$  influx pathway in *mdx* myocytes.<sup>16</sup> Here, we used confocal imaging with various fluorescent indicators to monitor intracellular processes that may link the initial transmembrane  $\text{Ca}^{2+}$  influx to cell damage. We observed that *mdx* cardiac myocytes exhibit an extreme  $\text{Ca}^{2+}$  signalling response to mechanical stress. More importantly, we identified an abnormal activation of the  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release signalling pathway together with an increased generation of reactive oxygen species (ROS) as two synergistic mechanisms contributing to the amplification of these  $\text{Ca}^{2+}$  signals. Preliminary results of these studies have been published as an abstract.<sup>17</sup>

## 2. Methods

### 2.1 Cell isolation

Ventricular myocytes were enzymatically isolated from 5- to 9-month-old mice as previously described.<sup>18,19</sup> The study conforms with the *Guide for the Care and Use of Laboratory Animals* published by the US National Institutes of Health (NIH Publication No. 85-23, revised 1996). C57BL/10ScSn-*mdx* and wild-type (WT) mice with identical genetic background (5-10 months old) were provided by Drs M. Rüegg (University of Basel, Switzerland), U. Rüegg (University of Geneva, Switzerland), or purchased from the Jackson laboratory (USA).

### 2.2 Experimental solutions

The isotonic superfusion solution contained (in mM): 140 NaCl, 5.4 KCl, 1.8  $\text{CaCl}_2$ , 1.1  $\text{MgCl}_2$ , 5 HEPES, and 10 glucose. The osmolality was  $\sim 310$  mosm/kg, and pH 7.3. The hypotonic solution contained 70 mM NaCl instead of 140 mM, had osmolality  $\sim 170$  mosm. Zero  $\text{Ca}^{2+}$  solution contained 2 mM EGTA. Where indicated, apocynin or ryanodine and thapsigargin were added for at least 30 min before the experiment. Most chemicals were obtained from Sigma. Mn-cpx 3 and apocynin were from Calbiochem, ryanodine from Alamone. All experiments were performed at room temperature ( $20$ – $22^\circ\text{C}$ ).

### 2.3 Confocal microscopy

Changes in cytosolic and mitochondrial  $[\text{Ca}^{2+}]$ , ROS production, and mitochondrial membrane potential were monitored with fluorescent indicators fluo-3 AM ( $5\text{ }\mu\text{M}$ ), rhod-2 AM ( $5\text{ }\mu\text{M}$ ), fura-red AM ( $5\text{ }\mu\text{M}$ ), 5-(and-6)-chloromethyl-2',7'-dichlorodihydrofluorescein diacetate (CM-H<sub>2</sub>DCFDA;  $20\text{ }\mu\text{M}$ ), and tetramethylrhodamine ethyl ester (TMRE;  $100\text{ nM}$ ), as previously described.<sup>20–22</sup> As a rule, cells were incubated with indicators for 30 min at room temperature, followed by at least 15 min for de-esterification. Resting  $[\text{Ca}^{2+}]$  and  $\text{Ca}^{2+}$  influx were measured with a double-indicator ratiometric procedure, which simultaneously utilizes fluo-3 and fura-red indicators to correct for dye dilution during osmotic swelling.<sup>23</sup> Fluo-3 AM was from Biotium, other indicators were from Invitrogen. A laser-scanning confocal microscope (Radiance, Bio-Rad) was used to acquire confocal images.<sup>22,24</sup> Fluo-3, fura-red, and CM-H<sub>2</sub>DCFDA were excited with the 488 nm line of an Argon laser. TMRE and rhod-2 were excited with a HeNe laser at 543 nm. The emitted light was collected above 500 nm and above 570 nm, respectively. The emission of fluo-3 and fura-red was simultaneously recorded with two PMTs using 515/30 and  $>600$  nm emission filters and the ratio calibrated according to.<sup>23</sup>

### 2.4 Data analysis

Analysed data are represented as mean  $\pm$  SEM. Where stated, statistical significance was determined using Student's *t*-test or the log-rank test. In the figures, single asterisk indicates  $P < 0.05$ , double asterisks indicate  $P < 0.01$ .

## 3. Results

### 3.1 Osmotic shock triggers excessive cytosolic $\text{Ca}^{2+}$ signals in *mdx* but not wild-type cardiomyocytes

We applied osmotic shocks to mimic some of the pathophysiological conditions of mechanical stress encountered by the cell *in vivo*.<sup>5,25</sup> Hypotonic solution induces cell swelling and mechanical deformation of the cell membrane. Cytosolic  $\text{Ca}^{2+}$  transients were recorded in both WT and *mdx* cardiomyocytes loaded with fluo-3. As a rule, series of 100 XY confocal scans were acquired at 0.5 Hz. Exposure of the cardiac myocytes to hypotonic solution (170 mosm) for 40 s consistently resulted in reversible cell swelling (by  $15.8 \pm 1.5\%$ ,  $n = 34$ ). In 82% of *mdx* myocytes (19 out of 23 cells), the return to isotonic solution caused extreme cytosolic  $\text{Ca}^{2+}$  signals such as bursts of  $\text{Ca}^{2+}$  sparks and repetitive  $\text{Ca}^{2+}$  waves exhibiting amplitudes comparable with normal  $\text{Ca}^{2+}$  transients (as shown in Figure 1A, left panel). In the majority of *mdx* cells, these  $\text{Ca}^{2+}$  signals lasted for the full duration of the recording (up to 3 min). In contrast, in only 47% of the WT cardiomyocytes, osmotic shock produced  $\text{Ca}^{2+}$  signals (nine out of 19 cells) and these were mostly moderate and short-lived (Figure 1A, right panel). The typical  $\text{Ca}^{2+}$  responses in *mdx* and WT

**Figure 1** Stress-induced intracellular  $\text{Ca}^{2+}$  signals in *mdx* and wild-type (WT) mouse ventricular myocytes. (A) Images of  $\text{Ca}^{2+}$ -related fluorescence (fluo-3) obtained in *mdx* (left) and WT (right) myocytes subjected to osmotic shock.  $\text{Ca}^{2+}$  sparks and  $\text{Ca}^{2+}$  waves appear after the shock, much more pronounced in the *mdx* myocyte (left panel). (B) Time course of normalized fluorescence pooled from this protocol in *mdx* (black circles) and WT myocytes (white circles). Line on the top represents the protocol by which extracellular solutions were changed. (C) Mean values of normalized fluorescence averaged for each cell during 60 s after the osmotic shock (for B and C:  $n = 23$  cells from  $N = 4$  mice for *mdx* and  $n = 19$ ,  $N = 3$  for WT).

cells are also visualized in movies in the online supplement. Figure 1B shows the averaged changes in intracellular fluorescence in all studied WT and *mdx* cardiomyocytes, normalized to the resting values before osmotic shock. The stress-induced increase in fluorescence was larger and longer lasting in *mdx* cells compared with WT myocytes. The mean cellular fluorescence signal recorded during the first 60 s after returning to the iso-osmotic solution was 6-fold larger in *mdx* cells (Figure 1C).

### 3.2 A small $\text{Ca}^{2+}$ influx is required for stress-induced $\text{Ca}^{2+}$ signals in *mdx* cardiomyocytes

The above observation together with the recent results by Yasuda *et al.*<sup>15</sup> suggest that *mdx* myocytes are more susceptible to membrane damage than WT cardiomyocytes. To test whether these  $\text{Ca}^{2+}$  signals depend on extracellular  $\text{Ca}^{2+}$ , we briefly removed  $\text{Ca}^{2+}$  from the extracellular solution. Figure 2 shows that switching to a solution containing 0 mM  $\text{Ca}^{2+}$  completely abolished the response to osmotic shock. This observation confirms that  $\text{Ca}^{2+}$  entry is required, although the precise pathway(s) leading to  $\text{Ca}^{2+}$  influx into dystrophic cells are yet to be established and seems to involve multiple molecular entities.<sup>3</sup>

Nevertheless, the increase in plasmalemmal permeability to  $\text{Ca}^{2+}$  and the slightly elevated resting  $\text{Ca}^{2+}$  concentration in *mdx* myocytes (see Figure 2E and Williams and Allen<sup>16</sup>) alone are unlikely to explain the sustained  $\text{Ca}^{2+}$  signals in *mdx* cells subjected to osmotic shock. In cells treated with ryanodine (5 μM) and thapsigargin (500 nM) to eliminate

the function of the sarcoplasmic reticulum (SR), a substantial  $\text{Ca}^{2+}$  influx during the superfusion with hypotonic solution would be visible as an increase of the cytosolic  $\text{Ca}^{2+}$  concentration. However, when applying a ratiometric indicator technique involving fluo-3 and fura-red to compensate for dye dilution due to osmotic swelling, only a modest elevation of the  $\text{Ca}^{2+}$  concentration was observed, suggesting that the  $\text{Ca}^{2+}$  influx was small (Figure 2C and D, gray circles).

### 3.3 Osmotic shock stimulates reactive oxygen species production

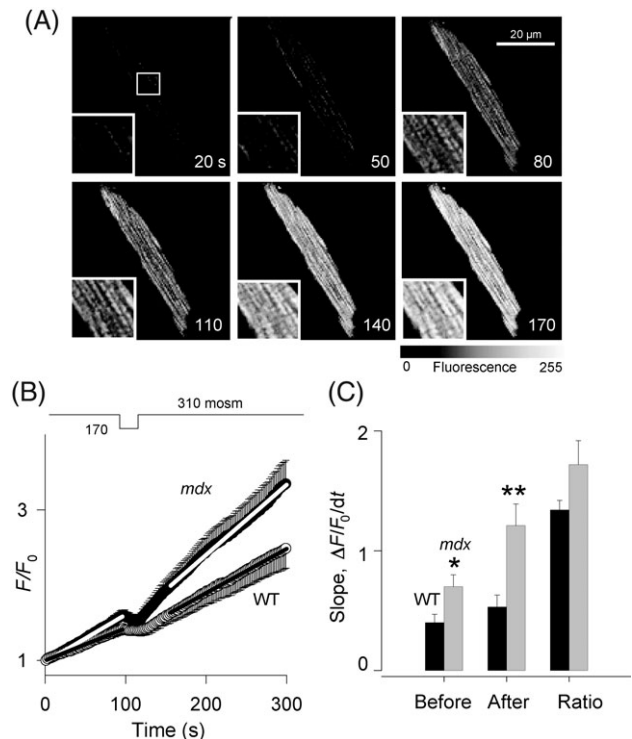

Because we were not able to detect a substantial  $\text{Ca}^{2+}$  influx during the shock, we suspected some intracellular mechanisms by which even small increases in  $[\text{Ca}^{2+}]_i$  due to  $\text{Ca}^{2+}$  influx were amplified. One possibility could be oxidation of the cytosolic environment due to excessive ROS production,<sup>26</sup> which could affect several proteins involved in intracellular  $\text{Ca}^{2+}$  homeostasis, most notably the ryanodine receptors (RyRs), thereby enhancing the sensitivity of SR  $\text{Ca}^{2+}$  release.

To test whether osmotic shock enhances ROS generation, we loaded myocytes with CM-H<sub>2</sub>DCFDA. In cells, this non-fluorescent compound is hydrolysed to DCFH and ROS generation is detected as a result of DCFH oxidation to DCF. Figure 3A shows images from one *mdx* cardiac myocyte before (image at 20 s), during (50 s), and after osmotic shock (80, 110, 140, and 170 s). Insets illustrate the banded fluorescence typical of a mitochondrial distribution. Figure 3B represents averaged and normalized

**Figure 2** Removal of extracellular  $\text{Ca}^{2+}$  prevents stress-induced  $\text{Ca}^{2+}$  signals while  $\text{Ca}^{2+}$  influx during osmotic shock is small. (A) Time course of averaged normalized fluorescence in *mdx* cells during the osmotic shock under control conditions (black circles) and when  $\text{Ca}^{2+}$  was briefly removed from the external solution (white circles). Bars at the bottom illustrate protocol by which extracellular solutions were changed. (B) Mean averaged fluorescence after the osmotic shock in the presence and absence of extracellular  $\text{Ca}^{2+}$  (for A and B:  $n = 5$  cells from  $N = 2$  mice for control and  $n = 6$ ,  $N = 2$  for zero  $\text{Ca}^{2+}$ ). (C) Time course of averaged fluo-3/fura red ratio in *mdx* myocytes in control (black circles) and in the presence of ryanodine (ry, 5  $\mu\text{M}$ ) and thapsigargin (tg, 0.5  $\mu\text{M}$ ) (gray circles). (D) Mean  $[\text{Ca}^{2+}]_i$  before, during, and 60 s after the osmotic shock in control ( $n = 7$ ,  $N = 3$ ) and in the presence of ryanodine and thapsigargin ( $n = 8$ ,  $N = 3$ ). (E) Mean resting  $[\text{Ca}^{2+}]_i$  in wild-type and *mdx* cardiomyocytes ( $n = 70$  and  $59$ ,  $N = 4$  and  $4$  mice).

changes in DCF fluorescence in *mdx* and WT cells. To quantify the stress-induced changes in ROS production, we performed a linear fit to the fluorescence signal in each cell before and after osmotic shock. The slope of the DCF signal reflects the rate of ROS production. Before the osmotic shock, the ROS-related signals rose monotonically, presumably due to a basal generation of ROS. The initial slope was significantly larger in *mdx* myocytes than in WT cells ( $0.70 \pm 0.09$ ,  $n = 12$  and  $0.40 \pm 0.07$ ,  $n = 9$ , respectively) indicating an oxidative stress in these cells, as also suggested in Williams and Allen.<sup>27</sup> Furthermore, we observed that the slope increased after the shock in both WT and *mdx* cells, but more in *mdx* myocytes than in WT cells [ratio of slopes before to after the shock was  $1.72 \pm 0.2$  ( $n = 12$ ) and  $1.34 \pm 0.12$  ( $n = 9$ ) in *mdx* and WT, respectively].

**Figure 3** *Mdx* cells generate more ROS than wild type and react more pronounced to osmotic shock. (A) Images of ROS related fluorescence (CM-H<sub>2</sub>DCFDA) in *mdx* myocytes exposed to osmotic shock (insets show magnified region of interest indicated in first panel). (B) Averaged changes in normalized ROS signal in *mdx* (black circles) and wild-type (WT) (white circles) cells. Lines represent linear fits to the data. (C) *Mdx* myocytes generate more background ROS and after the stress their production of ROS increases more than in WT cells ( $n = 12$  and  $9$ ,  $N = 3$  and  $3$  mice). See Supplementary Material online for colour version.

To confirm the involvement of ROS-dependent mechanisms in the generation of stress-induced  $\text{Ca}^{2+}$  signals, we incubated *mdx* myocytes with 10  $\mu\text{M}$  Mn-cpx3, a superoxide dismutase mimetic. Figure 4A shows that this ROS scavenger nearly eliminated cytosolic  $\text{Ca}^{2+}$  transients produced by osmotic shock. After washing out the scavenger for 30 min, five out of six *mdx* cardiomyocytes recovered their exacerbated response. Figure 4B shows a significant decrease in the mean intracellular fluorescence recorded during the first 60 s after returning to an iso-osmotic solution in the presence of the scavenger.

There are several possible sources of ROS in cardiac myocytes that may be activated in response to mechanical stress. NAD(P)H oxidase (NOX) is known to be overexpressed in dystrophic heart<sup>27</sup> and was found to be rapidly activated by osmotic swelling in astrocytes.<sup>28</sup> Therefore, we tested whether NOX could be a source for a rapid increase in the ROS production in response to the mechanical stress in *mdx* myocytes. Cells were incubated for 30 min with the NOX inhibitor apocynin (0.2–1 mM). Figure 4C and D shows that the drug nearly eliminated the intracellular  $\text{Ca}^{2+}$  signals induced by osmotic shock, suggesting NOX as a possible source of acute ROS production.

### 3.4 Excessive cytosolic $\text{Ca}^{2+}$ is taken up by the mitochondria

Mitochondria are well-established sources of ROS in myocardium subjected to acute or chronic mechanical stress.<sup>29</sup>

**Figure 4** Stress-induced  $\text{Ca}^{2+}$  signals depend on reactive oxygen species (ROS). (A) Time course of averaged normalized fluo-3 fluorescence in *mdx* cells subjected to osmotic shock under control conditions (black circles), after incubation with  $10 \mu\text{M}$  of the ROS scavenger Mn-cpx3 (white circles), and 30 min after its washout (gray circles). (B) Mean normalized fluorescence for data averaged during 60 s after the osmotic shock for control, Mn-cpx3, and after 30 min washout. Data for A and B are from  $n = 6, 6$ , and 11 cells,  $N = 3, 3$  and 3 animals, respectively. (C and D) Time course and averages showing suppression of the  $\text{Ca}^{2+}$  responses by the NOX inhibitor apocynin (data from  $n = 16$  and 27 cells,  $N = 4$  and 4 mice).

Mitochondrial ROS could be responsible for the sustained cellular  $\text{Ca}^{2+}$  signals observed in *mdx* myocytes (note the gradual increase in ROS-related fluorescence in the mitochondrial regions later during the experiment shown in Figure 3). It is known that muscle cells continuously generate ROS, as a by-product of the mitochondrial respiratory chain, and that enhanced mitochondrial  $\text{Ca}^{2+}$  uptake stimulates further mitochondrial ROS production. We tested whether and to what extent mitochondria take up cytosolic  $\text{Ca}^{2+}$  after osmotic shock.

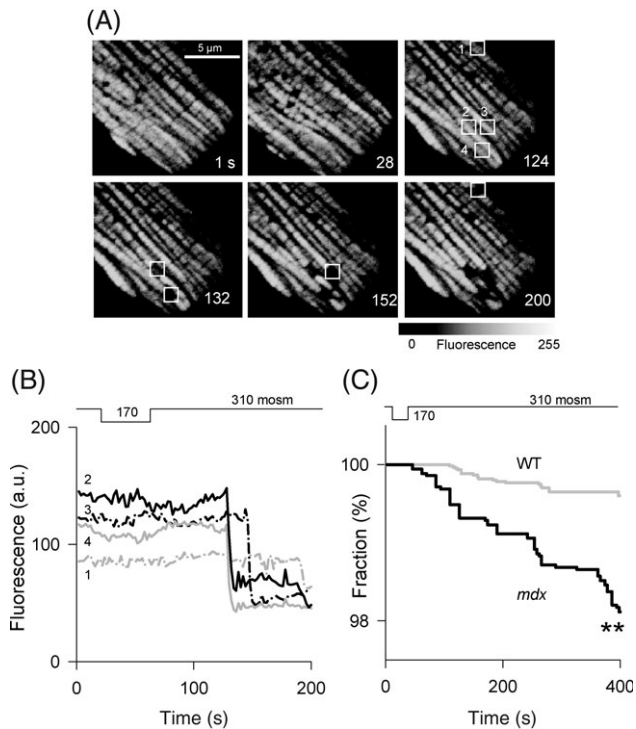

*Mdx* and WT myocytes were loaded with the  $\text{Ca}^{2+}$  indicator rhod-2 and imaged with the identical experimental protocol. Rhod-2 is a charged molecule that preferentially partitions into the mitochondria. Figure 5A shows the mitochondrial rhod-2 distribution and the fluorescence signal in *mdx* myocytes before (image at 1 s), during (image at 28 s), and after the shock. Following 40 s of osmotic shock, fluorescence gradually increased within all mitochondria. Figure 5B shows the time course of rhod-2 signals in three groups of mitochondria indicated in A. In some mitochondria, the rhod-2 signal, after an initial rise, decreased at later times, indicating a loss of rhod-2 and  $\text{Ca}^{2+}$ . Figure 5C represents averaged normalized changes in rhod-2 fluorescence in six *mdx* and eight WT cells, indicating that following osmotic stress mitochondria in *mdx* myocytes sequester significantly more  $\text{Ca}^{2+}$  which can add to the more pronounced ROS production.

**Figure 5** Excessive cytosolic  $\text{Ca}^{2+}$  is taken up by mitochondria. (A) Images of rhod-2 fluorescence in *mdx* myocyte undergoing osmotic shock. (B) Time course of rhod-2 signal in the groups of mitochondria indicated by regions of interest (1–3 in A). (C) Pooled data from *mdx* (black circles) and wild-type (white circles) cells studied with the same protocol. At the end of the recording, the mitochondrial  $\text{Ca}^{2+}$  accumulation is significantly more pronounced in *mdx* myocytes (data from  $n = 6$  and 8 cells,  $N = 2$  and 3 mice). See Supplementary Material online for colour version.

### 3.5 Osmotic shock induces mitochondrial depolarization in *mdx* cardiac myocytes

It is established that mitochondrial  $\text{Ca}^{2+}$  overload and the subsequent oxidative stress can lead to collapse of the mitochondrial membrane potential ( $\Delta\psi_m$ ) and/or to the opening of the mitochondrial permeability transition pore (mPTP), ultimately causing necrotic/apoptotic cell death.<sup>29</sup> Our results indicate that mitochondrial  $\text{Ca}^{2+}$  uptake is enhanced in *mdx* cardiac myocytes. We also found that some mitochondria lose  $\text{Ca}^{2+}$  after a period of initial accumulation, possibly as a result of irreversible mitochondrial depolarization.<sup>30</sup> Therefore, we carried out experiments to directly monitor changes in mitochondrial membrane potential. TMRE is a charged dye, which distributes across the mitochondrial membrane in a voltage-dependent manner. Whenever the potential across the mitochondrial membrane dissipates, TMRE fluorescence is lost. Figure 6A shows one *mdx* cardiomyocyte loaded with 100 nM TMRE. A single mitochondrion (or a small group of mitochondria) can be visualized in each of the marked boxes. Subsequent to the osmotic shock, some mitochondria displayed irreversible loss of  $\Delta\psi_m$  whereas others did not. Changes in TMRE fluorescence for four individual mitochondria are plotted in Figure 6B. Note that the final level of TMRE signal is essentially the same in all four organelles, indicating their complete depolarization. Figure 6C compares the incidence and timing of osmotic shock-induced mitochondrial depolarization in *mdx* and WT cardiomyocytes. For each time point, we

**Figure 6** Stress-induced collapse of mitochondrial membrane potential. (A) Images of TMRE fluorescence in an *mdx* myocyte subjected to osmotic shock. (B) Stepwise changes in fluorescence in boxed mitochondria in A suggest sudden loss of the membrane potential. (C) Fraction of mitochondria remaining polarized after osmotic shock in *mdx* (black line) and wild-type (gray line) myocytes. In *mdx* myocytes, significantly larger fraction of mitochondria loose their potential within the recording time (data from  $n = 10$  and 9 cells,  $N = 3$  and 3 mice). See Supplementary Material online for colour version.

calculated the number of polarized mitochondria in all cells of each type and normalized it to the total numbers of organelles imaged. In *mdx* cells, osmotic shock induced depolarization of  $\sim 2\%$  of the mitochondria within 400 s of experimental recording (black line). Loss of TMRE signals by individual mitochondria was observed already 4 s after the shock. In contrast, in WT myocytes, the fraction of depolarized mitochondria was much smaller (0.3%) and the onset was later (100 s after the shock). It should be mentioned that in some *mdx* myocytes shock induced severe mitochondrial depolarization waves that resulted in complete collapse of  $\Delta\psi_m$  across the entire cell within a few seconds. These cells were not included in the analysis presented in Figure 6C.

## 4. Discussion

Dystrophin-deficient cardiomyocytes are vulnerable to mechanical stress. Recently published work connects increased membrane fragility and stretch-induced  $\text{Ca}^{2+}$  influx with death of dystrophic cells.<sup>15</sup> In the present study, we identified two cellular signal amplification mechanisms that may link the fragility of the *mdx* cardiomyocyte membrane to later cell damage. As detailed below, the simultaneous activation of these two signal amplification systems is detrimental, because of bidirectional cross-talk

with positive feed-back. Thus, the cellular response proceeds beyond the physiological limits, culminating in a chain of events, which may later end in apoptotic and/or necrotic cell death.

### 4.1 Amplification mechanisms

The massive  $\text{Ca}^{2+}$  signals observed in *mdx* myocytes after osmotic shock were manifest as a surge of abundant spontaneous  $\text{Ca}^{2+}$  sparks, regularly blending into  $\text{Ca}^{2+}$  waves travelling along the cell. In resting cardiomyocytes such signals are the hallmark of abnormal  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release (CICR) activation and are commonly initiated by overloading the SR with  $\text{Ca}^{2+}$  in the course of various noxious conditions. The importance of CICR for the observed signal amplification was also emphasized by the absence of such  $\text{Ca}^{2+}$  signals in cells pretreated with ryanodine and thapsigargin. However, for  $\text{Ca}^{2+}$  overload to develop in a short period of time (i.e. during the exposure to hypotonic solution),  $\text{Ca}^{2+}$  influx has to be substantial. Surprisingly, such a massive  $\text{Ca}^{2+}$  influx could not be detected in our experiments, even though the behaviour of the myocytes in zero  $\text{Ca}^{2+}$  indicated an important role for at least some minor transsarcolemmal  $\text{Ca}^{2+}$  influx. The obvious discrepancy between massive and rapid CICR activation despite minimal  $\text{Ca}^{2+}$  entry and only slightly elevated resting  $\text{Ca}^{2+}$  levels led us to consider additional mechanisms that could make the RyRs rapidly more sensitive and provoke spontaneous  $\text{Ca}^{2+}$  signals without pronounced SR  $\text{Ca}^{2+}$  overload.

ROS have been implied in changing gating and  $\text{Ca}^{2+}$  sensitivity of the RyRs via redox modifications of the channels.<sup>31</sup> Furthermore, increased ROS generation after mechanical stretch has been reported even in normal cardiac muscle.<sup>26</sup> Our findings revealed an elevated basal rate of ROS production in *mdx* cells. Furthermore, mechanical stress led to enhanced ROS production in all cardiomyocytes, but significantly more pronounced in *mdx* cells. Although the first finding may underlie the propensity of *mdx* cells to overreact after small  $\text{Ca}^{2+}$  influx signals, the latter may be a consequence of the larger  $\text{Ca}^{2+}$  signals in these cells. As one might expect based on these findings, ROS scavengers reversibly suppressed the excessive stress-induced  $\text{Ca}^{2+}$  signalling in *mdx* cells. Taken together, our results suggest that the change of the cytosolic oxidative environment due to increased [ROS] promotes the abnormal CICR activation without pronounced  $\text{Ca}^{2+}$  overload.

ROS generation in response to mechanical forces may originate from several sources, including the NOX, xanthine oxidase, or other oxidase systems, such as nitric oxide oxidase, and mitochondria. Our results with the NOX inhibitor apocynin suggest an involvement of this source of ROS. Owing to its overexpression in dystrophic heart<sup>27</sup> and due to its rapid activation by osmotic swelling,<sup>28</sup> this source of ROS may be particularly important in the early phases of the response. It is also established that an elevation in mitochondrial  $[\text{Ca}^{2+}]$  subsequent to prolonged cytosolic  $\text{Ca}^{2+}$  signal activity stimulates mitochondrial ROS production.<sup>29</sup> Consistent with this notion, we observed increased  $\text{Ca}^{2+}$  levels in cardiac mitochondria following the osmotic shock that were significantly larger in *mdx* cells.

## 4.2 Cross-talk between $\text{Ca}^{2+}$ -induced $\text{Ca}^{2+}$ release and reactive oxygen species

CICR and ROS generation are two signalling pathways that exhibit a high degree of positive feed-back. Either mechanism could lead to the observed massive  $\text{Ca}^{2+}$  signals. However, the combination of both pathways being activated together may have even more severe consequences, as both pathways exhibit mutual and synergistic cross-talk with each other. For example, ROS could promote RyRs openings as well as further increase membrane fragility due to lipid peroxidation. In addition, ROS could stimulate  $\text{Ca}^{2+}$  influx into the cells via SAC and/or SOC, as some TRP channels (potential candidates for SOC and SAC) have been shown to be sensitive to the redox potential of the cytosol.<sup>3</sup> On the other hand, CICR and elevated  $[\text{Ca}^{2+}]_i$  favour mitochondrial ROS production, as discussed above. Taken together, the simultaneous activation of these signalling pathways is particularly destructive for the cells because it has a tendency to escalate into mutually synergistic positive feed-back signalling loops.

## 4.3 Link between abnormal cellular signalling and pathology of the heart

Although WT myocytes survive the initial  $\text{Ca}^{2+}$  overload, the strong activation of several pathways may overwhelm the cellular defence mechanisms in *mdx* cells. It has been postulated for many years that proteases are a downstream  $\text{Ca}^{2+}$ -activated target involved in protein degradation and necrosis of dystrophic skeletal muscle.<sup>3</sup> Calpain is considered to be a likely candidate, as its expression is greater in *mdx* muscle.<sup>3</sup> Because calpain is expressed in heart, and because calpain inhibitors protect from ischaemia-reperfusion injury,<sup>32</sup> it is likely that this protease forms a part of the cellular death pathway in *mdx* heart.

Under pathological conditions, cytosolic and mitochondrial  $\text{Ca}^{2+}$  overload and/or excess in ROS can lead to opening of the mPTP, which is accompanied by a dissipation of the mitochondrial membrane potential and usually precedes necrotic/apoptotic cell death.<sup>29,33</sup> Our data reveal multiple mitochondrial dysfunctions in *mdx* cardiac myocytes following osmotic stress. In particular, they show mitochondrial  $\text{Ca}^{2+}$  overload, increased ROS production, irreversible depolarization of the mitochondrial membrane, which can be a direct indication of mPTP opening. Apoptotic and necrotic cells have been observed in cardiac tissue of dystrophy patients and *mdx* mice. Lost cardiomyocytes cannot regenerate and are likely to be replaced by connective tissue, ultimately leading to the observed fibrosis.<sup>2</sup>

At present, several studies are conducted to develop treatments of the cardiac dystrophic phenotype by either replacing the lost cardiomyocytes with stem cell approaches<sup>34</sup> or to make the myocytes mechanically less vulnerable by gene transfer of dystrophin, utrophin, or functional dystrophin fragments (microdystrophins).<sup>35</sup> Notably, *mdx* mice can partly compensate for the lack of dystrophin by adaptive upregulation and redistribution of the protein utrophin.<sup>36</sup> An *mdx* mouse lacking utrophin presents with a more severe phenotype,<sup>37</sup> particularly in skeletal muscle, but also in cardiac muscle.<sup>38</sup> Although cell replacement therapies will obviously only be able to treat late stages of the disease, curative gene therapy may require a long time to develop for routine application. In the meantime,

it would be helpful to implement pharmacological treatment options which are able to slow down the progression of the disease.<sup>4</sup> Considering the early cellular stress responses reported here, this might be accomplished by interfering with any of the early cellular events leading to excessive  $\text{Ca}^{2+}$  and ROS signals.
