Increasing trends for invasive infections with extended-spectrum cephalosporin-resistant (ESC-R) Enterobacteriaceae have been described in many countries worldwide. However, data on the rates of ESC-R isolates in non-invasive infections and in the outpatient setting are scarce. We used a laboratory-based nationwide surveillance system to compare temporal trends of ESC-R rates in Escherichia coli and Klebsiella pneumoniae for in- and outpatients in Switzerland. Our data showed a significant increase in ESC-R rates from 1% to 5.8% in E. coli (p<0.001) and from 1.1% to 4.4% in K. pneumoniae (p=0.002) during an eight-year period (2004–2011). For E. coli, the increase was significantly higher in inpatients (from 1.2% to 6.6%), in patients residing in eastern Switzerland (from 1.0% to 6.2%), in patients older than 45 years (from 1.2% to 6.7%), and in male patients (from 1.2% to 8.1%). While the increase in inpatients was linear (p<0.001) for E. coli, the increase of ESC-R K. pneumoniae isolates was the result of multiple outbreaks in several institutions. Notably, an increasing proportion of ESC-R E. coli was co-resistant to both trimethoprim-sulfamethoxazole and quinolones (42% in 2004 to 49.1% in 2011, p=0.009), further limiting the available oral therapeutic options.

Introduction
Extended-spectrum cephalosporins (ESCs), such as those of third-generation (3GC, e.g. ceftriaxone, cefotaxime, ceftazidime) and fourth-generation (4GC, e.g. cefepime), are frequently used antibiotics for the treatment of severe infections, because of their ample spectrum, strong bactericidal activity, and low toxicity. However, during the past three decades, an increasing number of ESC-resistant (ESC-R) Gram-negative pathogens have been reported worldwide [1].

Several mechanisms such as production of extended-spectrum beta-lactamases (ESBLs), chromosomal (cAmpCs) or plasmid-mediated AmpCs (pAmpCs) or carbapenemases may lead to phenotypic resistance to ESCs. However, since their first description in 1983, ESBLs have been recognised as the most prevalent mechanism responsible for resistance to ESCs in Enterobacteriaceae. While ESBLs during the 1990s were mainly described in K. pneumoniae isolates causing nosocomial outbreaks, ESBL-producing E. coli causing community-acquired infections (especially urinary tract infections (UTIs)) nowadays also represent a serious challenge for the therapeutic armamentarium [2]. According to the Infectious Diseases Society of America (IDSA), ESBL-producing Klebsiella spp. and E. coli belong to the six most important multidrug-resistant (MDR) pathogens for which new therapies are urgently needed [3].

The prevalence of ESC-R Enterobacteriaceae varies worldwide. In 2009, 39% of E.coli isolated from intensive care patients in the Asian/Pacific area were ESBL producers, while rates were lower in Latin America (25%), Europe (16.3%) and North America (8.7%) [4]. As described by the European Antimicrobial Resistance Surveillance Network (EARS-Net), the prevalence rate of ESC-R Enterobacteriaceae causing invasive infections increased significantly from 2007 to 2010 in half of the reporting countries, but to different levels. For instance, while the rates in 2010 were below 5% in Scandinavia and Iceland, rates above 10% were found in 10 European countries (Bulgaria, Cyprus, Czech Republic, Greece, Hungary, Italy, Latvia, Malta, Romania and Spain) [5]. However, most surveillance programmes have taken into consideration only isolates responsible for invasive infections in hospitalised patients [6], and only a few studies at national and local level have described rates of ESBL producers in community-acquired UTIs or bloodstream infections (BSIs) [7-10]. As a result, data regarding the temporal
trends of antibiotic resistance in the community are still needed.

In this study, we describe in detail the temporal trends of ESC-R *E. coli* and *K. pneumoniae* isolates in hospital and community settings in Switzerland during an eight-year epidemiological study performed using the data of the Swiss Antibiotic Resistance Surveillance database ANRESIS [11].

**Methods**

**Data collection**
Antibiotic resistance data for *E. coli* and *K. pneumoniae* isolates were analysed using the ANRESIS database [11]. The ANRESIS programme collects all routine antibiotic resistance data from currently 22 clinical microbiology laboratories located in Switzerland. The ANRESIS laboratories are homogeneously distributed across the country. They include university laboratories, representing isolates mainly from tertiary-care hospitals, as well as cantonal and private laboratories, representing data from smaller hospitals and outpatient clinics. They send antimicrobial susceptibility test results (AST) of all routinely performed analyses, including isolates from non-sterile sites.

From 2004 to 2010, all participating laboratories interpreted their ASTs according to the Clinical Laboratory Standards Institute (CLSI) criteria in use at that time [12]. During 2011, five of the 11 laboratories included in this study changed their breakpoints according to the European Committee of Antimicrobial Susceptibility Testing (EUCAST) [13]. All institutions participated in at least one quality control programme from the United Kingdom National External Quality Assessment Service (UK NEQAS), and/or the National External Quality Program of the Institute of Medical Microbiology, Zurich [14]. AST results from each laboratory were sent on a regular basis, weekly or monthly, to the central database located at our institution (Institute for Infectious Diseases of the University of Bern).

For the present analysis, we used only data from the 11 laboratories sending data during the whole study period. These laboratories were representative for Switzerland. Moreover, hospitals performing fewer than 200 microbiological samples per year were excluded. Only clinical samples were analysed. When there were multiple isolates with an identical resistance pattern from the same patient and calendar year, only the first was included into the analysis. According to the hospital statistics of Switzerland for the year 2007 [16] and the statistics of Swiss physicians 2009 [17], the restricted data used for this analysis represent 30% of acute-care hospital beds in Switzerland and 11.2% of all Swiss family physicians. The number of BSIs was extrapolated using the 30% coverage of acute-care hospitals in this study.

**Interpretation of the results**
Resistant isolates were defined as those that were resistant or had intermediate susceptibility against the antibiotic tested. *E. coli* and *K. pneumoniae* isolates resistant to at least one 3GC and/or 4GC antibiotic were defined as ESC-R. The selection of 3GC and/or 4GC antibiotics tested differed between laboratories. If one antibiotic of an antibiotic class (e.g. quinolones or carbapenems) was resistant, the antibiotic class was classified as resistant. Results were stratified according to geographical region, in- versus outpatients (where outpatient was defined as a person attending a medical practice or outpatient clinic), age and sex of the patient, and whether the isolate was from UTI or BSI. For inpatients, nosocomial infection data (i.e. sample(s) positive for ESC-R isolates at least three days after hospitalisation) were analysed separately.

To examine seasonal trends, the period from April to September was defined as ‘summer season’, whereas that from October to March was defined as ‘winter season’. To compare prevalence rates of ESC-R *E. coli* and confirmed ESBL-positive *E. coli*, we used data from our own institution for the years 2009 and 2010. In this case, detection of ESBL producers was performed by double-disk synergy test (i.e. ceftriaxone, ceftazidime, cefpodoxime discs combined with an amoxicillin-clavulanate disc, distance centre-to-centre 20 mm).

**Statistical analysis**
To calculate 95% confidence intervals (CIs) of proportions, we used the modified Wald method [18]. Proportions were compared using two-tailed chi-square test or Fisher’s exact test using Epi info Version 3.4.3 (Centers for Disease Control and Prevention, Atlanta, United States). We analysed the time trends with linear regression using GraphPad Prism Version 5.04.

**Results**
The overall study included 160,010 *E. coli* and 21,290 *K. pneumoniae* isolates. ESBL confirmation was done for 225 ESC-R *E. coli* and 48 ESC-R *K. pneumoniae* isolated during the years 2009 and 2010 at the University Hospital of Bern. Of these, 210 (93.3%) *E. coli* and 46 (95.8%) *K. pneumoniae* isolates were confirmed as ESBL producers by the double disc synergy test.

During the eight-year period, a total of 63,743 *E. coli* (39.8%) and 11,083 (52.1%) *K. pneumoniae* were isolated from hospitalised patients from 34 different hospitals, and 96,267 *E. coli* (60.2%) and 10,207 *K. pneumoniae* (47.9%) isolates were collected from outpatients. Of the outpatient samples, 45,395 (47.2%) of *E. coli* isolates and 4,746 (46.5%) of *K. pneumoniae* isolates were collected in outpatient clinics, the rest were collected by general physicians.

**Escherichia coli**
Between 2004 and 2011, the prevalence of ESC-R *E. coli* increased significantly from 1.0% to 5.8% (p<0.001).

* Significance level indicating the probability that the slope of the linear regression using data of all years between 2004 and 2011 equals 0.
* Significance level indicating the probability that the slopes in the subgroups are equal by chance.
* South-western Switzerland includes the cantons Geneva, Vaud, Neuchâtel, Jura, Fribourg, Valais and Ticino; eastern Switzerland includes all other cantons.
* Other sample locations are not shown, therefore figures do no sum up to the total number.
* Sex was not specified for six *E. coli* isolates.
**Figure 1**
Co-resistance rates for ESC-R and non-ESC-R *Escherichia coli* and *Klebsiella pneumoniae* isolates, Switzerland, 2004–11

ESC-R: extended-spectrum cephalosporins-resistant; SXT: trimethoprim-sulfamethoxazole.
Resistance rates and 95% confidence intervals for different antibiotics for ESC-R and non-ESC-R *E. coli* and *K. pneumoniae* for the years 2004 to 2011. Fosfomycin and nitrofurantoin were not tested against *K. pneumoniae* isolates. Because of low numbers data are not shown for fosfomycin for the years 2004 to 2007. P values are given for significant trends only (p<0.05).
Figure 2
Increase in ESC-R rates in *Escherichia coli* and *Klebsiella pneumoniae* in 34 hospitals in Switzerland, 2004–11

**E. coli**

**A.** Means and standard error of the means of ESC-R prevalence rates in 34 Swiss hospitals from 2004 to 2011. The linear regression showed significant increase over time for *E. coli* and *K. pneumoniae* (*p* < 0.001 for both), correlation was linear for *E. coli* (*p* < 0.001) and *K. pneumoniae* (*p* = 0.007).

**B.** Rates of ESC-R isolates for individual hospitals. While the increase of ESC-R rates was steady and comparable in all hospitals for *E. coli*, we observed high variability between different years and hospitals for *K. pneumoniae.*

**K. pneumoniae**

**A.**

**B.**

ESC-R: extended-spectrum cephalosporins-resistant; *p*: significance for correlation; *r*: Pearson's correlation index.

A. Means and standard error of the means of ESC-R prevalence rates in 34 Swiss hospitals from 2004 to 2011. The linear regression showed significant increase over time for *E. coli* and *K. pneumoniae* (*p* < 0.001 for both), correlation was linear for *E. coli* (*p* < 0.001) and *K. pneumoniae* (*p* = 0.007).

B. Rates of ESC-R isolates for individual hospitals. While the increase of ESC-R rates was steady and comparable in all hospitals for *E. coli*, we observed high variability between different years and hospitals for *K. pneumoniae.*
This time trend was linear and without seasonality (data not shown). This increase in rates of ESC-R isolates was observed in all patient groups analysed and was significantly more pronounced in inpatients (p=0.027), in eastern Switzerland (p=0.037), in male patients (p<0.001), and those older than 45 years (p<0.001) (Table). There was no difference between patients under 15 and those 15–45 years of age, or between the age groups 45–65 years and over 65 years, although there was a trend for lower resistance in children younger than two years compared with those 2–15 years-old (p=0.055). We noted a significant increase of ESC-R isolates (from 0.6% in 2004 to 3.5% in 2011; p<0.001) in female patients aged between 15 and 45 years. For the non-ESC-R isolates, rates increased significantly over time for sulfamethoxazole-trimethoprim (SXT; 20.9% in 2004 versus 24.0% in 2011, p<0.001), quinolones (10.3% in 2004 versus 17.4% in 2011, p<0.001), the combined resistance to SXT and quinolones (7.1% in 2004 versus 10.1% in 2011, p<0.001), piperacillin-tazobactam (1.6% in 2004 versus 3.0% in 2011, p=0.005), and gentamicin (3.8% in 2004 versus 4.9% in 2011, p<0.001). For the ESC-R E. coli, we observed an increase in co-resistance to gentamicin (28.2% in 2004 versus 33.6% in 2011, p=0.013), SXT (52.9% in 2004 versus 60.1% in 2011, p=0.015), and combined resistance to SXT and quinolones (42.0% in 2004 versus 49.1% in 2011, p=0.009), and a non-significant increasing resistance rate for quinolones alone (58.0% in 2004 versus 67.8% in 2010, p=0.06).

The co-resistance rates to other antibiotic classes are shown in Figure 1. Rates were significantly higher for ESC-R than non-ESC-R E. coli isolates. Co-resistance did not differ between in- and outpatients (data not shown). For the non-ESC-R E. coli isolates, rates increased significantly over time for sulfamethoxazole-trimethoprim (SXT; 20.9% in 2004 versus 24.0% in 2011, p<0.001), quinolones (10.3% in 2004 versus 17.4% in 2011, p<0.001), the combined resistance to SXT and quinolones (7.1% in 2004 versus 10.1% in 2011, p<0.001), piperacillin-tazobactam (1.6% in 2004 versus 3.0% in 2011, p=0.005), and gentamicin (3.8% in 2004 versus 4.9% in 2011, p<0.001). For the ESC-R E. coli, we observed an increase in co-resistance to gentamicin (28.2% in 2004 versus 33.6% in 2011, p=0.013), SXT (52.9% in 2004 versus 60.1% in 2011, p=0.015), and combined resistance to SXT and quinolones (42.0% in 2004 versus 49.1% in 2011, p=0.009), and a non-significant increasing resistance rate for quinolones alone (58.0% in 2004 versus 67.8% in 2010, p=0.06).
Klebsiella pneumoniae

Overall, from 2004 to 2011 ESC-R K. pneumoniae isolates increased significantly from 1.1% to 4.4% (p=0.002). The increase was comparable in all patient subgroups (Table) and significant and linear in inpatients (Table, Figure 2A). However, in contrast to ESC-R E. coli, the Pearson’s correlation index was lower due to higher variability between different years in single hospitals (Figure 2B). Furthermore, ESC-R K. pneumoniae isolates were more frequently isolated from other sites than blood or urine than ESC-R E. coli (34.3% K. pneumoniae versus 17.4% E. coli, p<0.001). In particular, about two thirds of these non-blood, non-urine ESC-R K. pneumoniae were isolated from wounds or respiratory samples (Figure 3).

As shown in Figure 1, co-resistance in ESC-R K. pneumoniae exceeded 50% for all antibiotic classes tested except for aminoglycosides (gentamicin 30.8% and amikacin 6.0%) and carbapenems (4.1%) in 2011. These resistance rates were significantly higher in ESC-R than in non-ESC-R K. pneumoniae isolates. While there was no significant trend in co-resistance in ESC-R K. pneumoniae, we observed a significant increase in resistance in non-ESC-R K. pneumoniae for amoxicillin-clavulanate (5.1% in 2004 versus 11.5% in 2011, p=0.035), piperacillin-tazobactam (2.3% in 2004 versus 8.3% in 2011, p=0.030), and for double resistance to SXT and quinolones (2.5% in 2004 versus 5.3% in 2011, p=0.028).

Discussion

Increasing rates of ESC-R Enterobacteriaceae have been described worldwide, however most data rely on BSIs in inpatients [2,6,20]. Data on prevalence of ESC-R isolates among outpatients are rare and restricted to single years (e.g. France, 2006 [7]; Italy, 2003 [8]; Spain, 2006 [9]; Turkey, 2007 [10]). Only one of these studies compared rates of ESC-R Enterobacteriaceae among in- and outpatients [8], and data regarding temporal trends among outpatients are missing. Here, we present the temporal trends of ESC-R E. coli and K. pneumoniae among outpatients and compare the epidemiology of in- and outpatients from 2004 to 2011.

E. coli

According to EARS data, rates of ESC-R E. coli isolated from BSIs in 2003 increased from 2.7% in 2003 to 8.2% in 2009 [21]. Although such prevalence was lower in our population (1.5% in 2004 and 6.2% in 2011), the increasing trend was comparable with the above European data. We calculated an annual incidence of 2.9/100,000 cases of BSI due to ESC-R E. coli in 2011, which is in the same range as the average of 2.6/100,000 cases described in the 31 countries participating in EARS in 2007 [21]. The societal and economic burden of infections due to ESC-R E. coli is remarkable. Taking into consideration the morbidity and mortality data available in the literature, we would estimate 58 additional deaths and 1,131 additional hospital days attributable to BSI due to ESC-R E. coli in 2011 in Switzerland [22]. Extrapolating to other clinical manifestations, such as lower respiratory tract infections, skin and soft tissue infections and UTIs, we would expect 838 infections leading to 131 deaths and 9,233 additional days of hospitalisation [23] in Switzerland during the year 2011.

Rates of ESC-R E. coli increased steadily in all patient subgroups analysed, but especially in patients older than 45 years, in male patients and inpatients. This observation probably reflects the higher prevalence of established risk factors for infections due to ESBL producers in these sub-populations, such as older age, diabetes mellitus, prostate disease, previous antibiotic use, indwelling catheters, recurrent UTIs, recent hospital admission and residence in long-term care facility [24-30].

Rates of ESC-R E. coli also increased significantly over time in lower risk populations, such as young women and outpatients. This correlates well with European studies demonstrating increasing faecal carriage rates of ESBL-producing E. coli in the outpatient setting [31-34]. In Switzerland, a recent study detected ESBL-producing E. coli in 5.8% of routine stool samples from staff members of meat-processing companies [35], whereas as many as 15.2% of pigs and 17.1% of cattle at slaughter carried ESBL-producing E. coli, indicating that there is an established reservoir of these organisms in farm animals in Switzerland [36].

Co-resistance in ESC-R E. coli is frequent and at least in part due to the fact that genes coding for the resistance to different antibiotics are located on the same plasmids [6]. In our study, roughly half of ESC-R E. coli were resistant to both SXT and quinolones. Resistance rates to these antibiotics increased over time, whereas resistance to nitrofurantoin and fosfomycin did not increase between 2004 and 2011, indicating that both antibiotics are still a valuable alternative for non-complicated UTIs [37]. For invasive infections, carbapenems are still a valuable option, but it is feared that spread of carbapenemase producers (e.g. KPC and NDM producers) will increase the incidence of MDR bacteria [38].

K. pneumoniae

K. pneumoniae is the second most frequent cause of Gram-negative BSIs after E. coli and often affects patients with impaired immune system such as patients with diabetes, alcohol problems and hospitalised patients with indwelling devices [5]. In our population, BSIs due to K. pneumoniae in 2011 were eight times less frequent than those due to E. coli.

As for E. coli, prevalence rates of ESC-R K. pneumoniae are increasing worldwide. Between 2007 and 2010 rates of ESC-R K. pneumoniae increased significantly in nine of 28 countries participating in EARS, leading to very different rates (from below 1% in northern countries to greater than 50% in some south-eastern countries) [6]. Restricting our analysis to blood cultures, we
observed an increase in ESC-R isolates from 1.4% in 2004 to 3.5% in 2011 (p=0.05), which is comparable to the northern countries of Europe [5].

As for *E. coli*, rates of ESC-R *K. pneumoniae* increased in all patient subgroups but, in contrast to *E. coli*, there were no differences by age or sex. Resistance to other antibiotic classes was even higher than in *E. coli*. Indeed, ESC-R *K. pneumoniae* resistance rates in 2011 were above 50% for all antibiotics tested except aminoglycosides and carbapenems. Carbapenemase resistance in ESC-R *K. pneumoniae* increased from 0% to 4.1%, which was not significant (p=0.11). However, in view of the global epidemiology, this finding probably anticipates a worrisome expansion of these life-threatening pathogens [39].

In contrast to *E. coli*, infections with ESC-R *K. pneumoniae* are still mainly hospital-associated [40], with outbreaks more frequently reported for ESC-R *K. pneumoniae* than for ESC-R *E. coli* [41,42]. This is supported by our analysis demonstrating that the increase of infections due to ESC-R *K. pneumoniae* was more pronounced in inpatients, which is mainly due to the accumulation of multiple small outbreaks in single hospitals (see Figure 2b). Several reasons for the higher frequency of outbreaks in *K. pneumoniae* have been postulated: (i) environmental contamination occurs significantly more often when the patient is carrying ESBL-producing *K. pneumoniae* compared with ESBL-producing *E. coli* [41]; (ii) *K. pneumoniae* has a higher ability to persist in the environment due to the formation of biofilms [43]; (iii) some antiseptics (e.g. chlorhexidine or hexamidine) are less effective against *K. pneumoniae* [44]. In addition, our data demonstrate that ESC-R *K. pneumoniae* were more frequently isolated from wounds or the respiratory tract, which may facilitate transmission, when standard hygiene precautions are not implemented.

Our study has several limitations. Because physicians frequently implement an empirical treatment for UTIs and provide a urine sample only if the infection does not improve, our analysis may overestimate the real incidence of ESC-R [45]. In addition, it is important to note that our study describes the epidemiology of ESC resistance, which includes ESBL, pAmpCs and cAmpCs. However, our data are consistent with those of the European Center for Disease Prevention and Control (ECDC), which also use ESC-R as a surrogate for ESBL production, demonstrating that 65 to 100% of ESC-R *E. coli* in Europe are ESBL producers [5]. We were not able to perform genetic analysis to confirm the presence of ESBL genes in our collection of isolates. Performing phenotypic ESBL confirmation tests in a subset of our samples, we speculate that about 93 to 96% of ESC-R isolates in Switzerland are true ESBL producers. However, the clinical impact of confirming ESBL production is debated, and newer guidelines even abstain from confirmatory tests and at least for clinical decisions completely rely on phenotypic resistance testing results [46,47].

In conclusion, we demonstrate a significant increase of ESC-R *E. coli* and *K. pneumoniae* isolates in the period from 2004 to 2011 in Switzerland. This increase is comparable to other European countries. Our data allowed us to demonstrate an increase in ESC-R in non-invasive and in outpatient samples and to estimate the burden of disease in Switzerland. National surveillance should be implemented and maintained to monitor the spread of life-threatening MDR pathogens and support physicians in the implementation of correct and efficacious antibiotic treatments in community and hospital settings.

Acknowledgements

For development and support of the ANRESIS database we obtained financial support from the Swiss National Science Foundation, the Swiss Federal Office of Public Health, the Swiss Conference of the Cantonal Ministers of Public Health and the University of Bern. We thank all ANRESIS laboratories for providing their resistance data. This manuscript is dedicated to Kathrin Mühlemann who was very engaged in building up ANRESIS, but unfortunately died before completion of this manuscript.
