The aim of the present study was to investigate the effects of different speech tasks (recitation of prose (PR), alliteration (AR) and hexameter (HR) verses) and a control task (mental arithmetic (MA) with voicing of the result) on end-tidal $\text{CO}_2$ (ET-$\text{CO}_2$), cerebral hemodynamics; i.e. total hemoglobin (tHb) and tissue oxygen saturation (StO$_2$). tHb and StO$_2$ were measured with a frequency domain near infrared spectrophotometer (ISS Inc., USA) and ET-$\text{CO}_2$ with a gas analyzer (Nellcor N1000). Measurements were performed in 24 adult volunteers (11 female, 13 male; age range 22 to 64 years) during task performance in a randomized order on 4 different days to avoid potential carry over effects. Statistical analysis was applied to test differences between baseline, 2 recitation and 5 recovery periods. The two brain hemispheres and 4 tasks were tested separately. Data analysis revealed that during the recitation tasks (PR, AR and HR) StO$_2$ decreased statistically significant ($p < 0.05$) during PR and AR in the right prefrontal cortex (PFC) and during AR and HR in the left PFC. tHb showed a significant decrease during HR in the right PFC and during PR, AR and HR in the left PFC. During the MA task, StO$_2$ increased significantly. A significant decrease in ET-$\text{CO}_2$ was found during all 4 tasks with the smallest decrease during the MA task. In conclusion, we hypothesize that the observed changes in tHb and StO$_2$ are mainly caused by an altered breathing during the tasks that led a lowering of the $\text{CO}_2$ content in the blood provoked a cerebral $\text{CO}_2$ reaction, i.e. a vasoconstriction of blood vessels due to decreased $\text{CO}_2$ pressure and thereby decrease in cerebral blood volume. Therefore, breathing changes should be monitored during brain studies involving speech when using functional near infrared spectroscopy (fNIRS) to ensure a correct interpretation of changes in hemodynamics and oxygenation.
