Toll-Like Receptor 2–Deficient Mice Are Highly Susceptible to \textit{Streptococcus pneumoniae} Meningitis because of Reduced Bacterial Clearing and Enhanced Inflammation

Hakim Echchannaoui,\textsuperscript{1} Karl Frei,\textsuperscript{1} Christian Schnell,\textsuperscript{2} Stephen L. Leib,\textsuperscript{3} Werner Zimmerli,\textsuperscript{1} and Regine Landmann\textsuperscript{1}\textsuperscript{1}Division of Infectious Diseases, Department of Research, University Hospital, and \textsuperscript{2}Division of Angiogenesis Platform, Pharma Novartis, Basel, \textsuperscript{3}Department of Neurosurgery, University Hospital, Zürich, and \textsuperscript{4}Institute for Infectious Diseases, University of Bern, Bern, Switzerland

Toll-like receptor–2 (TLR2) mediates host responses to gram-positive bacterial wall components. TLR2 function was investigated in a murine \textit{Streptococcus pneumoniae} meningitis model in wild-type (wt) and TLR2-deficient (TLR2$^{-/-}$) mice. TLR2$^{-/-}$ mice showed earlier time of death than wt mice ($P<.02$). Plasma interleukin-6 levels and bacterial numbers in blood and peripheral organs were similar for both strains. With ceftriaxone therapy, none of the wt but 27% of the TLR2$^{-/-}$ mice died ($P<.04$). Beyond 3 hours after infection, TLR2$^{-/-}$ mice had higher bacterial loads in brain than did wt mice, as assessed with luciferase-tagged \textit{S. pneumoniae} by means of a Xenogen-CCD (charge-coupled device) camera. After 24 h, tumor necrosis factor activity was higher in cerebrospinal fluid of TLR2$^{-/-}$ than wt mice ($P<.05$) and was related to increased blood-brain barrier permeability (Evans blue staining, $P<.02$). In conclusion, the lack of TLR2 was associated with earlier death from meningitis, which was not due to sepsis but to reduced brain bacterial clearing, followed by increased intrathecal inflammation.

\textit{Streptococcus pneumoniae} is the major cause of meningitis in adults. Despite antimicrobial therapy and critical care medicine, the mortality remains as high as 28% [1]. In addition, 50% of the survivors have neurologic sequelae, indicating postinflammatory damage [2]. In the pathogenesis of meningitis, penetration of bacteria through the blood-brain barrier (BBB) initiates activation of brain endothelia and leads to leukocyte recruitment and release of inflammatory mediators. Subsequently, the subarachnoidal inflammation stimulates astrocytes, microglia, and neurons to produce cytokines and chemokines [3–5]. A bacterial level of $\geq 5$ log cfu in the brain initiates a harmful inflammatory cascade, which causes development of symptoms and determines the prognosis [6]. Pneumococci enter into the cerebral compartment through the BBB via binding of their cell-wall component phosphorylcholine to the platelet-activating factor receptors expressed on activated cells [7, 8]. In view of the finding that antagonists of the platelet-activating factor receptor do not completely block bacterial invasion [7, 8], other cell-wall components, such as peptidoglycan and lipoteichoic acid, might also induce inflammation via activation of pattern recognition receptors expressed in these cells [9]. Toll was first cloned in \textit{Drosophila} species [10] and was found to be involved in host defense against fungal infection [11]. In humans, 10 homologous genes have been identified encoding Toll-like receptors (TLRs) [12–14]. TLR2 is involved in cell activation by gram-positive bacterial cell wall and membrane components, such as peptidoglycan, lipoteichoic acid, and lipoproteins [15–17]. Accordingly, macrophages isolated from TLR2-deficient (TLR2$^{-/-}$) mice are hyporesponsive to \textit{Staphylococcus aureus} peptidoglycan stimulation [18]. Despite growing evidence implicating TLR2 in recognition of gram-positive bacterial cell-wall components in vitro, its role in bacterial meningitis is still unknown. In this study, we compared disease severity and outcome in TLR2$^{-/-}$ and wild-type (wt) mice in an adult mouse model of \textit{S. pneumoniae} and \textit{Listeria monocytogenes} meningitis. Bacterial numbers in the brain, bacterial counts, and leukocyte recruitment into the subarachnoid space, as well as meningeal inflammation and BBB permeability, were analyzed.

Materials and Methods

Preparation of bacterial inocula. \textit{S. pneumoniae} (clinical isolate of serotype 3) was grown for 7 h in double Mueller-Hinton broth...
(Difco Laboratories), subcultured overnight in new Mueller-Hinton broth, and washed in 0.9% sterile saline (12,000 g for 6 min) immediately before use. The inoculum size was calculated from optical density determinations (optical density of 0.4 = \(1 \times 10^4\) cfu) and was retrospectively assessed by counting colony-forming units on blood agar plates. *L. monocytogenes* (strain EGD; provided by R. M. Zinkernagel, University Hospital, Zürich) was grown overnight at 37°C, yielding 1–2 \(10^5\) cfu in trypticase soy broth (BBL Microbiology Systems).

**Mouse meningitis models.** Six- to eight-week-old C57BL/6 wt (RCC) and TLR2\(^{-/-}\) mice (provided by William J. Rieflin, Tularex, South San Francisco, CA; mice had been back-crossed for 6 generations on a C57BL/6 background) were kept under specific pathogen-free conditions. Mice were anesthetized via intraperitoneal injection of 100 mg/kg ketamine (Ketalar; Warner-Lambert) and 20 mg/kg xylazine (Xylapan; Graeub) and subsequently inoculated intracerebrally into the left forebrain with either 0.9% NaCl, live *S. pneumoniae* (\(2 \times 10^6\) or \(3 \times 10^7\) cfu), or live *L. monocytogenes* (\(5 \times 10^6\) cfu) in a 25-\(\mu\)L volume. In addition to the intracerebral inoculation, selected experiments were done by an intracisternal route of infection, as described elsewhere for experimental meningitis in infant rats [19]. Mice (\(n = 10\) each C57BL/6 wt and TLR2\(^{-/-}\)) were deeply anesthetized and infected by direct intracisternal injection of 10 \(\mu\)L of saline containing 8.5 \(10^6\) cfu/mL *S. pneumoniae* by means of a 32-gauge needle.

The health status of the mice was assessed by the following scores, as described elsewhere [20]: 1, exhibited normal motor activity and turned upright in <5 s when put on its back; 2, showed decreased spontaneous activity, but still turned upright in <5 s; 3, turned upright in 5–10 s; 4, did not turn upright; or 5, did not move. After 6, 12, 24, 48, and 72 h or if they presented with a score of 5, mice were killed by intraperitoneal injection of 100 mg/kg pentobarbital (Abbott Laboratories). Blood was obtained by intracardiac puncture and collected in EDTA. Animals were perfused with Ringer’s solution (Braun Medical) into the left cardiac ventricle until the effluent became clear. Cerebrospinal fluid (CSF) was obtained by puncture of the cisterna magna, as described elsewhere [21]. Because of the small volumes (3–6 \(\mu\)L) obtained from each animal, CSF from 4 mice was pooled.

Selected mice were treated with 80 mg/kg ceftriaxone (Rocephin; Hoffmann-La Roche) dissolved in 0.1 mL of saline via intraperitoneal injection twice daily for 5 days. Treatment was started 18 h after infection. For the leukocyte depletion treatment, cyclophosphamide (Sigma) was reconstituted with sterile PBS and injected intraperitoneally (250 mg/kg in 0.2 mL) 48 h before infection. Brains were obtained by puncture of the cisterna magna, as described elsewhere [23]. Evans blue (0.2 mL, 2% in NaCl; Sigma) was injected into the tail vein of infected (24 or 48 h) mice 60 min before death. Mice were perfused as described above, their brains were removed, and the hemispheres were separated. Each hemi-

**Determination of bacterial counts and inflammatory parameters.** Brains were homogenized with a Polytron homogenizer in 1 mL of 0.1 mol/L PBS. Bacterial titers were determined by plating serial 10-fold dilutions in 0.9% NaCl on blood agar plates. The concentration of the proinflammatory cytokine tumor necrosis factor (TNF) in plasma and CSF was determined with a bioassay, measuring the degree of cytotoxicity on WEHI cells in the presence 1 \(\mu\)g/mL actinomycin D, with use of mouse recombinant TNF as a standard. Interleukin (IL)-6 in plasma was measured by a mouse IL-6 ELISA kit (OptEIA; PharMingen).

**Evolution of BBB integrity.** BBB permeability was assessed by measuring Evans blue extravasation, according to a method described elsewhere [23]. Evans blue (0.2 mL, 2% in NaCl; Sigma) was injected into the tail vein of infected (24 or 48 h) mice 60 min before death. Mice were perfused as described above, their brains were removed, and the hemispheres were separated. Each hemi-

NOTE. Female mice (6-8-weeks old) were infected intracerebrally with 5 x 10<sup>7</sup> cfu of *L. monocytogenes* in 25 μL of NaCl.

*Log-rank test in Kaplan-Meier analysis.

TLR2<sup>−/−</sup> mice were infected intracerebrally with *S. pneumoniae*. The severity of the disease was monitored by assessing both the clinical score and the survival rate. Infected mice remained free of clinical signs of meningitis at 6 and 12 h after infection but had gradually reduced spontaneous activity between 12 and 24 h (data not shown). As shown in figure 1A, both wt and TLR2<sup>−/−</sup> mice became severely sick during *S. pneumoniae* meningitis. The percentage of severely ill mice was significantly higher among TLR2<sup>−/−</sup> than control mice after 72 h (P < .02, repeated-measures analysis of variance). Indeed, only 30% of TLR2<sup>−/−</sup> mice survived at 72 h, and all died at 102 h after infection (figure 1B), whereas 60% of the wt mice survived at 72 h and died of *S. pneumoniae* meningitis later (136 h after infection). TLR2<sup>−/−</sup> mice also showed reduced survival time (P < .02, Kap-

Results

**TLR2<sup>−/−</sup> mice have a higher susceptibility to *S. pneumoniae* and *L. monocytogenes meningitis**. To evaluate the in vivo role of TLR2 during gram-positive bacterial meningitis, wt and TLR2<sup>−/−</sup> mice were infected intracerebrally with *S. pneumoniae* or *L. monocytogenes*. The severity of the disease was monitored by assessing both the clinical score and the survival rate. Control animals, injected with 0.9% NaCl, showed no altered health status. Infected mice remained free of clinical signs of meningitis at 6 and 12 h after infection but had gradually reduced spontaneous activity between 12 and 24 h (data not shown). As shown in figure 1A, both wt and TLR2<sup>−/−</sup> mice became severely sick during *S. pneumoniae* meningitis. The percentage of severely ill mice was significantly higher among TLR2<sup>−/−</sup> than control mice after 72 h (P < .02, repeated-measures analysis of variance). Indeed, only 30% of TLR2<sup>−/−</sup> mice survived at 72 h, and all died at 102 h after infection (figure 1B), whereas 60% of the wt mice survived at 72 h and died of *S. pneumoniae* meningitis later (136 h after infection). TLR2<sup>−/−</sup> mice also showed reduced survival time (P < .02, Kap-

to cure the sepsis. It is known that wt mice treated in the first 24 h after infection with ceftriaxone (80 mg/kg every 12 h for 5 days) survive without apparent signs of meningitis [25]. Delay of treatment beyond 30 h leads to death in >50% of the infected mice [25]. We treated infected mice with ceftriaxone after *S. pneumoniae* infection, and the obtained clinical scores and survival rates of both ceftriaxone-treated and control mice are shown in table 2. With ceftriaxone treatment, all wt mice survived without any clinical signs of disease after 6 days, whereas 4 (27%) of 15 TLR2−/− mice died despite treatment ($P < .04$, Kaplan-Meier analysis). As described above, all untreated wt and TLR2−/− mice died within 4–6 days (data not shown). Treatment failure in TLR2−/− mice could be explained by the fact that at the initiation of the treatment (18 h after infection), 7% of TLR2−/− mice but none of the wt mice were severely sick. By day 6, 27% of the treated TLR2−/− mice remained severely ill and subsequently died, whereas all wt mice recovered during treatment.

**TLR2−/− mice have a higher bacterial load in brain and stronger meningeal inflammation after intracerebral infection with S. pneumoniae than do wt mice.** To further explain the high susceptibility of TLR2−/− mice to *S. pneumoniae* meningitis, we examined bacterial counts, leukocyte recruitment, and TNF release in the CSF as well as bacterial densities in the brain. Monitoring of meningitis in animals intracerebrally injected with luciferase-tagged *S. pneumoniae* revealed a higher fluorescence intensity in TLR2−/− brains than in wt brains between 2 and 24 h after infection (figure 4A). Twenty-four hours after infection, mice were
Meningeal inflammation, as assessed by TNF activity in the CSF, was significantly higher in TLR2−/− mice than in wt mice 24 h after infection with S. pneumoniae (1077 ± 201 and 705 ± 74 pg/mL of CSF, respectively; P < .02; figure 5C). Early after infection, at 6 and 12 h, TNF activity was low or below detection (<20 pg/mL), and, after 48 h, the difference between TLR2−/− mice and wt mice was no longer statistically significant, because of high variability (figure 5C).

An association between disease severity and meningeal inflammation was documented by a significant relationship between TNF activity in the CSF and severity score 24 h after infection (r = 0.589; P < .001; data not shown). Thus, the level of TNF in CSF might reflect the intensity of clinical signs during the first day of infection.

To investigate whether infiltrating leukocytes contribute to meningeal inflammation during S. pneumoniae meningitis, we analyzed TNF activity in the CSF in infected mice rendered leukopenic by cyclophosphamide. As shown in figure 6, TNF activity was significantly decreased in leukopenic TLR2−/− mice, compared with immunocompetent mice 24 h after infection (P < .05). In contrast, no difference in TNF activity was observed in wt mice with or without cyclophosphamide pretreatment.

**TLR2−/− mice have enhanced BBB permeability after intracerebral infection with S. pneumoniae.** Alteration of the BBB is a consequence of meningeal inflammation. Therefore, we analyzed changes in BBB permeability during S. pneumoniae meningitis with the Evans blue extravasation method.

Measures of BBB permeability and severity of the disease in wt and TLR2−/− mice are presented in table 3. Infection with S. pneumoniae induced alteration of the BBB in both wt and TLR2−/− mice, as evidenced by higher Evans blue concentrations in brains of TLR2−/− mice, compared with control mice. This BBB disruption occurred early in disease (24 h) and was stronger in TLR2−/− mice than in wt mice. At the same time, TLR2−/− mice showed more severe symptoms of meningitis than did wt mice (table 3). In addition, meningeal inflammation, assessed by TNF in the CSF, was significantly related to BBB permeability (r = 0.768; P < .02; data not shown).

### Discussion

We have studied the in vivo role of TLR2 in an adult mouse model of S. pneumoniae meningitis. TLR2−/− mice had more severe clinical symptoms than did wt mice and subsequently showed earlier death. Similar results were obtained with L. monocytogenes as the infecting agent (table 1). This result is in agreement with a previous report on increased mortality of TLR2−/− mice from S. aureus sepsis [26]. In that model, TLR2−/− mice showed reduced systemic bacterial clearance, compared with wt mice, after a high but not after a low intra-

Note. Ceftriaxone treatment (80 mg/kg) was administered intraperitoneally every 12 h for 5 days, starting 18 h after intracerebral injection of 3 × 10^7 cfu of S. pneumoniae. P < .04, TLR2−/− vs. wt mice (log-rank test in Kaplan-Meier analysis).

killed, and the photon emission was stronger and more widely spread in isolated brains of TLR2−/− mice than in those of wt mice (figure 4A). In particular, signals from bacteria were differentially distributed in TLR2−/− and wt mice. In contrast to the picture in wt mice, bacteria were not accumulated in the ventricles of TLR2−/− mice but concentrated on the ipsilateral and contralateral sides of the injection site. Furthermore, a quantitative time course analysis of emitted fluorescence from infected animals showed a more rapid bacterial growth in TLR2−/− mice than in wt mice when the intracisternal route of infection was used (median, cfu and cfu in 771.8 and 778.2, respectively; ; Mann-Whitney test). In particular, signals from bacteria were differentially distributed in TLR2−/− and wt mice. Figure 4.  

A. Time course of infection in wild-type (wt) and Toll-like receptor-2–deficient (TLR2−/−) mice after intracerebral injection of 3 × 10⁶ cfu of luciferase-tagged Streptococcus pneumoniae. Images from 1 animal in each group at time of infection (0 h) and 2, 4, 6, 12, and 24 h after infection and isolated brains 24 h after infection are shown. B. Emitted light was also quantified by LivingImage software (Xenogen) and shown as bacterial growth gradient (calculated as ratio between emitted photons and time elapsed after infection). Results from individual mice are shown, with median (horizontal line). **P < .0001, repeated-measures analysis of variance (ANOVA) (n = 11 and n = 10 at 2 and 4 h, n = 10 and n = 9 at 6 and 12 h, and n = 6 and n = 5 at 24 h, for wt and TLR2−/− mice, respectively).

venous inoculum. According to the authors, this was due to failure to recognize invading bacteria [26]. Instead, in our model with a low inoculum in the brain, systemic host defense was not impaired in the absence of TLR2, because similar plasma levels of IL-6 and numbers of bacteria were observed in blood and organs of TLR2−/− and wt mice. Moreover, in ceftriaxone-injected animals, in which the infection is successfully treated, 27% of the TLR2−/− mice died, whereas all wt mice survived.
Figure 5. Time course of cerebrospinal fluid (CSF) parameters in wild-type (wt) and Toll-like receptor-2–deficient (TLR2<sup>−/−</sup>) mice (at each time point in both groups) after intracerebral injection of 3 × 10<sup>5</sup> cfu of Streptococcus pneumoniae. Pooled CSF from 4 mice was collected at indicated times after infection. Infiltrating leukocytes (A), bacterial numbers (B), and tumor necrosis factor (TNF) levels (C) were analyzed in CSF. Results of 3 independent experiments are shown as mean ± SD. When errors bars are not seen, they fall within mean symbol. *P < .05 and **P < .02, both by the Wilcoxon signed rank test. 

This indicates that the higher mortality in TLR2<sup>−/−</sup> mice was not due to defective bacterial clearance in the periphery.

We observed more bacteria in the brains, but not in the CSF, of TLR2<sup>−/−</sup> mice. More rapid growth, which was detectable as early as 2 h after infection, was associated with a protracted accumulation of the bacteria around the site of injection in TLR2<sup>−/−</sup> mice. This was in contrast to wt mice, in which the bacteria were mainly in the ventricles after 24 h. It is known that TLR2 is constitutively expressed in the choroid plexus and the lateral ventricle lining [27]. It can be hypothesized that the lack of TLR2 in the choroidal epithelia and/or endothelia and in the ependymal cells contributed to the particular distribution pattern of the bacteria by altering the CSF flow. The different localization of the bacteria in brains of wt and TLR2<sup>−/−</sup> mice probably also explains why the numbers of colony-forming units in CSF were similar in both strains.

Leukocyte infiltration following bacterial invasion into the central nervous system is correlated with brain edema and injury in bacterial meningitis [28, 29]. The rapid increased bacterial growth in brain homogenates of TLR2<sup>−/−</sup> mice may, in turn, have contributed to the enhanced inflammation and to the earlier aggravation of the symptoms in these animals. Despite higher bacterial numbers in brain, pleocytosis was not significantly different in wt and TLR2<sup>−/−</sup> mice, except for a transient delay in leukocyte recruitment 12 h after infection in TLR2<sup>−/−</sup> mice. Perhaps the delayed leukocyte influx into the CSF could be explained by a lack of TLR2 action on integrin or intercellular adhesion molecule (ICAM) expression, because it has been shown that blocking of the integrin CD18 and of the adhesion molecule ICAM attenuated meningeal inflammation and tissue damage [30, 31]. However, it is also possible that the recruitment of leukocytes may have been delayed in TLR2<sup>−/−</sup> mice because of the lack of TLR2 activity on IL-8 [32]. Indeed, a previous study showed that intravenous treatment with antibody against IL-8 attenuates the neutrophil pleocytosis during experimental pneumococcal meningitis [33].

Despite the slower early influx of leukocytes, we observed higher TNF activity during S. pneumoniae meningitis in CSF of TLR2<sup>−/−</sup> than of wt mice. TNF is elevated in CSF in human and experimental meningitis. It has detrimental effects, because its neutralization decreases meningeal inflammation, as shown in a rabbit pneumococcal meningitis model [34, 35]. However, the total lack of TNF also adversely effects host defense in meningitis. Indeed, mice with a targeted deletion of TNF die earlier
Table 3. Blood-brain barrier permeability and clinical score in Toll-like receptor-2-deficient (TLR2<sup>−/−</sup>) and wild-type (wt) mice after intracerebral injection of $3 \times 10^5$ cfu of *Streptococcus pneumoniae*.

<sup>a</sup> Data are median (range) clinical score. See Materials and Methods for a description of the scoring system.

<sup>b</sup> Data are mean ± SD fold increase, compared with uninfected control mice.

The consequence of meningeal inflammation is an alteration of the BBB integrity. In the present study, the BBB disruption was markedly increased in TLR2<sup>−/−</sup> mice, compared with control mice, and was related to TNF levels in the CSF. This corroborates the known role of TNF in BBB disruption and consequently in the course of disease [35, 37, 38].

Our observation of a stronger in vivo TNF induction in TLR2<sup>−/−</sup> than in wt mice is in contrast to the reduced in vitro TNF production of TLR2<sup>−/−</sup> in macrophages in response to *S. aureus* [26]. However, an important difference in our experimental model is the use of live bacteria, whereas that study [26] was conducted with heat-killed bacteria. We therefore conclude that live *S. pneumoniae* and their turnover products induce TNF differently than do heat-killed bacteria. It is likely that, during infection, other receptors are activated together with TLR2. The nature of these other receptors is not clear. They could be other TLRs, such as TLR1 and TLR6, which are also triggered by bacterial products [39]. In this case, their stimulation led to the release of large amounts of TNF, which are higher than those induced in the presence of TLR2. This might occur because these TLRs show sequence similarities in their intracytoplasmic regions and then share common transducing mechanisms. Other receptors involved in this signaling could be specific for *S. pneumoniae* products, such as platelet-activating factor receptors [7] or C-reactive protein [40]. Finally, another possibility is that triggering of TLR2 on a particular cell type only might lead to the regulation of TNF. However, in this case, it is not clear how the engagement of TLR2 would down-regulate the TNF release.

The same accelerated death rate as for those infected with *S. pneumoniae* was also observed in *Listeria*-infected TLR2<sup>−/−</sup> mice, yet they and *Listeria*-infected wt mice had similar TNF activity in the CSF (data not shown). This suggests that different mechanisms are involved in *S. pneumoniae* and *L. monocytogenes* meningitis.

As reported elsewhere, in *L. monocytogenes* meningitis, monocytes contributed to the leukocyte infiltration in CSF, whereas *S. pneumoniae* meningitis caused only polymorphonuclear leukocyte accumulation [41]. Together with our recent observation that TLR2 protein is constitutively expressed in mouse polymorphonuclear leukocytes, but not in macrophages (authors’ unpublished data), the excess TNF in *S. pneumoniae* meningitis may be polymorphonuclear leukocyte–derived. To confirm this hypothesis, we investigated which cells contributed to the TNF release in the subarachnoid space during *S. pneumoniae* meningitis. Depletion of leukocytes by cyclophosphamide treatment before infection led to a decrease in TNF level in TLR2<sup>−/−</sup> but not in wt mice. This result validated that leukocytes participated in TNF production but were not the only source of TNF in TLR2<sup>−/−</sup> mice. Brain microvascular endothelia have been shown to produce TNF in pneumococcal meningitis or after stimulation with cell walls of *S. pneumoniae* [7, 42]. Furthermore, we and others could show that primary cultures of astrocytes, microglial cells, and neurons release TNF after stimulation with live *S. pneumoniae* (authors’ unpublished data) and pneumococcal cell wall components [43].

In conclusion, the mouse *S. pneumoniae* meningitis model described here is fatal for both wt and TLR2<sup>−/−</sup> mice. The clinical course of meningitis, the number of bacteria, the level of meningeal inflammation, and BBB damage are aggravated in mice lacking TLR2. Taken together, these results indicate, for the first time, a contribution of TLR2 in regulation of bacterial clearing and inflammatory response in pneumococcal meningitis.
