Background—Over the past 15 years, a myriad of mutations in genes encoding cardiac ion channels and ion channel interacting proteins have been linked to a long list of inherited atrial and ventricular arrhythmias. The purpose of this study was to identify the genetic and functional determinants underlying exercise-induced polymorphic ventricular arrhythmia present in a large multigenerational family.

Methods and Results—A large 4-generation family presenting with exercise-induced polymorphic ventricular arrhythmia, which was followed for 10 years, was clinically characterized. A novel SCN5A mutation was identified via whole exome sequencing and further functionally evaluated by patch-clamp studies using human embryonic kidney 293 cells. Of 37 living family members, a total of 13 individuals demonstrated ≥50 multiform premature ventricular complexes or ventricular tachycardia upon exercise stress tests when sinus rate exceeded 99±17 beats per minute. Sudden cardiac arrest occurred in 1 individual during follow-up. Exome sequencing identified a novel missense mutation (p.I141V) in a highly conserved region of the SCN5A gene, encoding the Na_+ 1.5 sodium channel protein that cosegregated with the arrhythmia phenotype. The mutation p.I141V shifted the activation curve toward more negative potentials and increased the window current, whereas action potential simulations suggested that it lowered the excitability threshold of cardiac cells.

Conclusions—Gain-of-function of Na_+ 1.5 may cause familial forms of exercise-induced polymorphic ventricular arrhythmias. (Circ Cardiovasc Genet. 2014;7:771-781.)

Key Words: arrhythmia (heart rhythm disorders) ■ catecholaminergic polymorphic ventricular tachycardia ■ exercise test ■ genetic testing ■ mutation ■ SCN5A

Since 1995, a myriad of mutations in the genes coding for cardiac ion channel subunits or proteins interacting with ion channels were described in patients with inherited forms of arrhythmic disorders, such as congenital long QT syndrome (LQTS), Brugada syndrome (BrS), and catecholaminergic polymorphic ventricular tachycardia (CPVT), hence, defining cardiac genetic channelopathies. Most of these disorders have demonstrated a broad genetic and phenotypic heterogeneity. SCN5A is the gene encoding the pore-forming subunit, Na_+ 1.5, mediating the Na_+ current (I_{Na}) of cardiac cells. The arrhythmic phenotypes linked to the mutations in SCN5A are variable, including LQTS type 3, BrS, many forms of conduction defects, atrial fibrillation, sudden infant death syndrome, and dilated cardiomyopathy. More recently, 3 studies^4 have reported on a new SCN5A-dependent clinical presentation called multifocal ectopic Purkinje-related premature contractions caused by the mutation p.R222Q.
strong cosegregation with the symptomatic patients was found. Functional and computational studies suggest that the mutation-induced biophysical alterations lead to atrial, Purkinje cells, and ventricular hyperexcitability. These findings further expand the spectrum of cardiac arrhythmias caused by SCN5A variants.

Methods
A Finnish family with 37 living members in 4 generations was evaluated (Figure 1). Altogether 31 family members underwent cardiological examination, including electrocardiographic tests and cardiac ultrasonography between years 2002 and 2003. In 2013, at the end of the follow-up period, all family members were recontacted and invited for assessment of their symptoms and possible cardiovascular interventions. Informed consent was obtained from all patients. The study was performed in accordance with the Helsinki Declaration and was approved by the local ethical review board.

Electrocardiographic and Ultrasonographic Examinations
Standard ECG was recorded at rest (50 mm/s, 0.1 mV/mm). QT interval was measured from lead II and adjusted for heart rate (QTc) according to the Fridericia’s correction formula. Bicycle ergometer test was performed with continuous 12-lead ECG recording. The initial load was 30 W, followed by increments of 15 W each minute. The total number of PVCs and the maximum number of consecutive PVCs in ventricular salvos were counted during work phase. A 24-hour ambulatory ECG was recorded on an outpatient basis. Rhythm, mean heart rate, number of ventricular premature complexes, and number and maximum length of ventricular tachycardias (≥3 consecutive ventricular complexes) were calculated.

Echocardiography was performed using parasternal long- and short-axis and apical 4-chamber views. Aortic root dimension was measured at the sinus vasaform level. Left ventricular dimensions and wall thickness were measured from the M-mode recordings. Doppler echocardiography was used to exclude any valvular stenosis or regurgitation.

Phenotypic Classification of Family Members
Patients with ≥50 polymorphic PVCs or >10 polymorphic PVCs per minute or ventricular tachycardia during exercise stress test (ET) were considered affected. Individuals who were unable to perform an ET were classified as unknown.
Sequencing of Candidate Genes
Mutations in RYR2 were excluded by sequencing its all translated exons and exon-intron boundaries in the DNA sample of the proband (AMC, University of Amsterdam, Netherlands).

Whole exome sequencing of 8 affected pedigree members was performed using the NimbleGen SeqCapEZ sequence capture technology (www.nimblegen.com/products/seqcap/ez/index.html). The exome targets of the patients’ DNA were captured with the NimbleGen SeqCap Ez Human Exome Library v2.0, followed by sequencing with the Illumina Genome Analyzer-Ix platform at the Technology Center at the Institute for Molecular Medicine Finland. The alignment to human reference genome hg19 and variant calling of chromosomal regions with a sequence-coverage of 29x was performed using the variant calling pipeline of the Institute for Molecular Medicine Finland. The data were filtered to capture only rare coding variants, that is, variants giving rise to missense, nonsense, splice site, or frame shift mutations either with minor allele frequencies <0.005 or not at all present in the 1000 genomes catalogue of human genetic variation (http://browser.1000genomes.org/index.html). The presence of a chr3:38,663,952 T>C variant in the SCN5A gene, initially identified by exome sequencing, was assessed in all affected and unaffected family members by direct Sanger sequencing using forward primer 5’TACACCTACTGACATACCTGG 3’ and reverse primer 5’TTCTGGACGACCTGTTAGTGG 3’. The sequencing reactions were run on an Applied Biosystems 96-capillary 3730xl DNA Analyzer and analyzed with the Variant Reporter software (Applied Biosystems, US) at the Technology Center at the Institute for Molecular Medicine Finland. The predicted effect of the rare coding SCN5A variant identified was analyzed by PolyPhen2 (http://genetics.bwh.harvard.edu/pph2/) and SIFT (http://sift.jcvi.org/).

Microsatellite Genotyping
Genome-wide linkage mapping was performed using ABI PRISM Linkage mapping Set MD10 (Applied Biosystems). Standard PCR protocols were used for amplification of microsatellite fragments using 10 ng of genomic DNA as a template. The fluorescently labeled PCR products were separated using ABI3730 (Applied Biosystems) automated electrophoresis system and the genotype calls were made using GeneMapper3.7 software. Two independent reviewers verified all allele calls, and any discrepancies were resolved. Genotypes were checked for violation of Mendelian segregation of alleles using PEDCHECK.11

Linkage Analysis
Linkage analysis using exercise-induced frequent polymorphic ventricular premature complexes during an exercise test as a dichotomized trait was performed using the program Merlin (http://www.sph.umich.edu/csg/abecasis/merlin/index.html). The analyses were run applying an affected-only approach in which the phenotype of all unaffected family members was assumed to be unknown, and the disease allele frequency was set to 0.0001.

Site-Directed Mutagenesis
Site-directed mutagenesis was performed on pCDN3.1-hSCN5A using the Quick-Change II XL site-directed mutagenesis kit (Stratagene) according to the manufacturer’s instructions. The construct was completely sequenced to ensure that there was no other mutation present.

Cell Culture
Human embryonic kidney 293 cells were cultured at 37°C in Dulbecco’s Modified Eagle Medium supplemented with 10% Fetal bovine serum, 4 mmol/L glutamine, and 20 mg/mL gentamicin in a humidified atmosphere of 5% CO2 and 95% air. All cell medium components, except glutamine (Sigma-Aldrich), were purchased from Gibco.

Cellular Electrophysiology
The human embryonic kidney 293 cells were transfected with DNA complexed to JetPEI (Polyplus-transfection) according to the manufacturer’s instructions. DNA concentrations were 1 μg of pCDN3.1-Na 1.5 wild type (WT), p1137V, or p1141V and 1 μg of pRES-hs1-CD8. The resulting Na1.5 protein is a splice variant lacking a glutamine at position 1077 (Q1077del). Eight hours after transfection, the cells were isolated and seeded in plastic Petri dishes at low density. Twenty-four hours after transfection, the resulting sodium current (INa) was recorded at room temperature (23–25°C) under whole-cell voltage clamp conditions with an Axopatch 200B (Axon Instruments, Inc) amplifier interfaced to a personal computer and driven by the PClamp 10 software (Molecular Devices Corporation). Capacitance and series resistances were compensated (60% to 80% compensation), and the residual capacitive currents were cancelled using a P/4 protocol. The cells were bathed with an extracellular solution containing (in mmol/L) NaCl 50, NMDG-Cl 80, CaCl2 1, MgCl2 1.2, CaCl2 2, HEPES 10, and glucose 5. The pH was adjusted to 7.4 with CsOH. Glass pipettes (tip resistance, 1.5–3 mol/LΩ) were filled with an intracellular medium containing (in mmol/L) CsCl 60, aspartic acid 50, CaCl2 1, MgCl2 1, HEPES 10, EGTA 11, and NaATP 5. The pH was adjusted to 7.2 with CsOH. For the window current measurements, the presented recordings are normalized to the peak current obtained at ~20 mV and are tetrodoxin (TTX)-subtracted (30 μM).

All products were purchased from Sigma, except TTX, which was obtained from Alomone.

Computer Simulations of INa* Action Potentials (AP), and Conduction
The INa and action potentials were simulated using the 10 Tusscher–Noble–Panfilov (TNPN) human ventricular cell model,12 the Courtemanche–Ramirez–Nattel human atrial cell model,13 and the Stewart–Aslanidi–Noble–Boytz–Zhang Purkine cell model.14 In all 3 models, INa is represented according to a Hodgkin–Huxley formalism, INa = gNa m3h(V − EK), where gNa is the maximal conductance of INa, m3h represents 3 activation gates, h and f are inactivation gates, V is the membrane potential, and EK is the Nernst potential of potassium. The INa formulation in the TNPN and Stewart–Aslanidi–Noble–Boytz–Zhang models, which are based on human INa recordings, are equivalent up to the maximal conductance of INa, but they differ in terms of steady state values and time constants of the different gates from the INa formulation in the Courtemanche–Ramirez–Nattel model, which is based on that of Luo and Rudy.15 Table 1 presents the modifications of INa that were introduced in the 3 models to match the experimental data.

Action potential propagation was simulated in a 1 cm long fiber based on the equation

\[ \frac{\partial V_m}{\partial t} = -I_{INa} + D \frac{\partial^2 V_m}{\partial x^2}, \]

where \( I_{INa} \) is the sum of the ionic currents normalized to cell capacitance and \( D \) is the diffusion constant, which depends on intra- and intercellular conductance and surface-to-volume ratio. For all 3 models, \( D \) was set to 0.00154 cm2/m as in the original TNPN model,15 which corresponds to the normal level of gap junctional coupling in the direction of myocardial fibers. Using the same \( D \) allows a direct comparison of conduction between the 3 models. Gating variables were integrated using the method of Rush and Larsen and the other model variables using the forward Euler algorithm, with \( \Delta t = 0.01 \) cm and \( \Delta x = 0.005 \) ms. The fiber was stimulated at 1 extremity and conduction velocity was computed using linear regression of activation times (occurrence of dV/dtmax) over a segment extending from 25% to 75% of fiber length. Of note, the computer simulations have the limitation that the models did not incorporate the effects of adrenergic stimulation. Of note, in the current study, we did not incorporate any variability in the computer simulations. All the used values are the arithmetic means of the given parameters.

WT denote the formulation of the original models. The shift parameters \( \sigma_i \) and \( \sigma_r \) were determined based on experimental data.

**Data Analysis and Statistical Methods**

Currents were analyzed with Clampfit software (Axon Instruments, Inc). Data were analyzed using a combination of pClamp10, Excel (Microsoft), and Prism (graphpad).

Comparisons between groups were performed with 2-tailed Student’s \( t \) test or ANOVA for normally distributed parameters. The Kolmogorov–Smirnov test was used to test the normality of the analyzed experimental data. Data are expressed as mean±SD. A \( P \) value <0.05 was considered significant.

**Results**

The structure of the Finnish family segregating the exercise-induced arrhythmia syndrome is shown in Figure 1A, and the findings of the electrocardiographic and cardiac ultrasonography studies are presented in Table 2. Of those alive in the 4-generation family, a total of 6 individuals had experienced a syncopal spell. One case of sudden cardiac death occurred during prospective follow-up. Family member II-1 had died at the age of 2 years. None of the family members had a documented coronary artery disease or a history of angina pectoris.

**ECC Registrations**

Of 16 adult Na_1.5 p.I141V mutation carriers, 5 presented with sinus rhythm, 1 with atrial flutter, and 11 with ectopic atrial rhythm in their resting ECG (Table 2; Figure 2A and 2B). Nodal escape rhythm was seen occasionally (Figure 2C). PVCs were not present in resting ECG in any of the family members at first examination. The sinus rate at rest was higher in Na_1.5 p.I141V mutation carriers than in noncarriers (Table 3). PQ and QT intervals, QRS complex morphology and duration, ST segment, and T-wave pattern were normal in all during sinus rhythm.

A total of 32 subjects were studied by repeated ETS. The first ET showed ≥50 PVCs during exercise in 10 and the subsequent ETS revealed the same in 3 additional individuals, all carriers of Na_1.5 p.I141V mutation. During the ETS, the ventricular arrhythmias progressively became more complex and abundant in parallel with the increasing sinus rate; examples are shown in Figure 2D and 2E. Some of the QRS complexes show varying morphology. In 9 out of 13 ET-positive subjects, arrhythmia progressed to nonsustained polymorphic ventricular tachycardia (≥3 successive complexes; Figure 2F). The average sinus rate at which the ventricular arrhythmias initially appeared was 99±17 beats per minute, and arrhythmias disappeared rapidly after discontinuation of exercise. The maximum sinus rate achieved during exercise was on average 97%±8% of the age-specific maximum.

**Cardiac Ultrasonography**

In cardiac ultrasonography, all Na_1.5 p.I141V mutation carriers showed normal left ventricular end-diastolic diameter and index (48±3 mm and 24.5±2.8 mm², respectively). Aortic root diameter was ≥44 mm in 3 of them.

**Detection of the SCN5A Mutation**

By using whole exome sequencing, we detected a novel nonsense mutation, (chr3:38,663,952 T>C) in SCN5A, encoding for the Na_1.5 sodium channel protein, in addition to 2 rare coding mutations, that is, rs148604148 (missense, MAF 0.002) in XYLB, encoding for xylulokinase homolog (H. influenzae) and rs141040660 (synonymous, MAF 0.0005) in ANO10, encoding for anotamin 10, that were shared by all 8 sequenced individuals. The 3 genes are located at 5 Mb distance from each other on chromosome 3p22.2, but only SCN5A is expressed in cardiac tissue and is known to be associated with several arrhythmia disorders, including congenital LQTS type 3, BrS, and idiopathic ventricular fibrillation.

Because the exome sequencing resulted in low coverage across chr3:38,663,952, ie, 3x to 9x, the initial analyses showed the presence of the chr3:38,663,952 T>C in SCN5A, encoding for the Na_1.5 sodium channel protein, in addition to 2 affected pedigree members in addition to 4 unaffected family members and 3 children with unknown phenotype carried the chr3:38,663,952 T>C mutation (representative sequence traces from 4 family members are presented in Figure 1B). Based on PolyPhen2 and SIFTanalyses, the mutation, which results in an isoleucine to valine substitution at position 141 of the Na_1.5 protein (p.I141V), was classified as possibly damaging with a score of 0.46 and deleterious with a score of 0.00, respectively. Moreover, the mutation seems to be unique to this family. It is not present in the published 1000 genomes data set, of which 83 are Finnish subjects, neither was it present in exome sequence data from 580 unrelated Finnish subjects (unpublished observation), further indicating that this sequence variant is rare. Finally, we performed linkage analyses to assess the probability that all affected individuals share a mutation. The chr3:38,663,952 T>C variant yielded a 2-point LOD-score of 3.56 (conservatively classifying only individuals with >50 exercise-induced polymorphic complexes as affected), whereas genome-wide linkage analyses of the whole pedigree utilizing microsatellite genotypes indicated that the chr3:38,663,952 T>C variant resided in the only chromosomal region displaying complete cosegregation with the arrhythmia phenotype. No mutations were found in the genes RYR2 and CASQ2.
Effects of p.I141V Mutation on Na_1.5 Channel Function in Human Embryonic Kidney 293 Cells

To investigate the functional consequences of the p.I141V mutation on the Na^+ channel activity, we used the whole-cell configuration of the patch-clamp technique. The presence of the mutation did not modify the Na^+ current density (Table A in the Data Supplement). The voltage-dependence of steady state activation was shifted toward more negative potentials (−7 mV) in the presence of the mutation (P < 0.01; Figure 3A and 3B; Table A in the Data Supplement). For a given command voltage, the activation and inactivation kinetics were accelerated in the mutant channel (Figure 3C and 3D). However, no significant differences were observed regarding the voltage dependence of steady state inactivation (Figure 3B; Table A in the Data Supplement), the recovery from fast inactivation (Figure 3E), and the onset and recovery from slow inactivation (Figure IA and IB in the Data Supplement).

Based on the negative shift of the steady state activation curve, we predicted an increase of the window sodium current (Figure 3B, inset). To investigate this window current, we examined the responses of cells transfected with Na_1.5 WT and p.I141V channels to a ramp voltage protocol, in which membrane potential was gradually changed between −100 and +50 mV at 0.5 mV/ms. Compared with the WT window current, the p.I141V window current exhibited a larger peak, and this peak was shifted toward more negative potentials (Figure 3F; Figure IC and ID in the Data Supplement).

The Importance of the p.I141 Residue on Na_1.5 Channel Function

The isoleucine 141 (I141) amino acid is highly conserved across species- and voltage-gated sodium channels isoforms (Figure 1C and 1D). The importance of the p.I141 position on Na_1.5 function was investigated by mutating the nearest and highly conserved isoleucine 137 to valine. Interestingly, this particular substitution (p.I137V) did not modify any of the Na_1.5 channel properties investigated (Figure II in the Data Supplement).
To investigate the functional consequences of the cardiac hyperexcitability because of the p.I141V mutation of Na\(_\text{v}1.5\), we incorporated the p.I141V Na\(_\text{v}1.5\) properties observed experimentally into the atrial Courtemanche–Ramirez–Nattel, the ventricular TNNP, and the Purkinje Stewart–Aslanidi–Noble–Noble–Boyett–Zhang cell models. The \(I_{Na}\) formulations in all models were modified to reproduce the biophysical changes caused by the p.I141V mutation (see Methods and Figure 4A–4C). In the \(I_{Na}\) formulations of all models, the effects of the p.I141V mutation were simulated by shifting the voltage dependence of the steady state equilibrium \(m_{\infty}\) and the time constant \(\tau_{m}\) of the \(m\) gates by an equal amount to recapitulate the shift of the steady state activation curve and the acceleration of activation and by shifting the voltage dependence of the closing rate constant \(\beta_{h}\) of the \(h\) gate to recapitulate the acceleration of fast inactivation with no change in the recovery from inactivation. The \(j\) gate was left unchanged. The formulations used are summarized in Table 1.

Simulations were run using the 3 cell models for WT, using both heterozygous and homozygous p.I141V genotypes, and the strength–duration curves were constructed. In the 3 models, a lower excitation threshold for action potential generation (pacing rates, 1 and 2.5 Hz for the atrial and ventricular models and 2.5 Hz for the Purkinje model) was observed in the homozygous and heterozygous p.I141V genotypes compared with the WT (Figure 4D–4I).

Interestingly, at both pacing rates, the strength–duration curve for
the heterozygous genotype was close to the curve for the homozygous genotype. In the Purkinje cell model, we observed that the p.I141V mutation accelerates the rate of spontaneous activity, even in the heterozygous state (Inset Figure 4F).

Conduction velocity was investigated in fibers of Courtemanche–Ramirez–Nattel, TNNP, and SANNBZ cell models (pacing rates, as described above). As shown in Figure 4J–4L, the presence of the p.I141V mutation in homozygous and heterozygous states accelerated atrial and ventricular conduction in a similar manner at 1 and 2.5 Hz, and it accelerated conduction in the Purkinje fiber at 2.5 Hz.

Clinical Follow-Up
During a follow-up of 10 years, altogether 38% of 16 adult Na,1.5 p.I141V carriers have either permanent (n=4) or paroxysmal (n=2) atrial fibrillation. At the end of the follow-up period, β-antiadrenergic medication was used by 10 individuals, 1 of whom was also using amiodarone. An implantable defibrillator (ICD) was implanted in another tertiary care center to 1 family member (II:14) because of nonsustained ventricular tachycardias. Left ventricular dilatation or systolic heart failure was detected in none of the family members during follow-up. The dilated aortic root had not required surgical intervention in any of the cases during follow-up.

Another family member (III-3) died during the follow-up 3 years after a mitral valve replacement. He had been followed from the age of 36 because of frequent multiformic PVCs, paroxysmal atrial fibrillation, and mitral valve prolapse. Perioperative pulmonary vein isolation was unsuccessful in eliminating AF.

Figure 3. Experimental effects of p.I141V mutation on Nav1.5 channel in human embryonic kidney 293 (HEK293) cells. A, Current traces obtained with a current/voltage protocol (see inset) from Na,1.5-WT and p.I141V transfected cells. Bold traces are the Na+ current at −40 mV. B, Steady-state activation (WT, n=8; p.I141V, n =9) and inactivation curves (WT, n=8; p.I141V, n =9). Activation properties were determined from I/V relationships by normalizing peak INa to driving force and maximal INa. Parameters for the voltage-dependence steady state of activation and steady state of inactivation (20-ms test pulse to −10 mV after a 500 ms conditioning prepulse) are summarized in Table in the Data Supplement. C, Sodium current time-to-peak values were used to evaluate the activation kinetics (WT, n=8; p.I141V, n =9). D, Fast inactivation time constants were measured by fitting the inactivation phase of the Na+ current to a single exponential equation for WT and p.I141V (WT, n=8; p.I141V, n =9). For C and D, a 2-way ANOVA test followed by a Bonferroni correction was used to compare point-by-point the measured activation and inactivation: ***P<0.001 vs WT. E, Recovery from fast inactivation was measured using the inset twin-pulse protocol (WT, n=8; p.I141V, n =9). F, Averaged normalized WT (n=13) and p.I141V (n=14) tetrodotoxin-sensitive window currents obtained with a 300 ms depolarizing-voltage ramp from −100 and +50 mV (0.5 mV/ms), normalized to the peak current at −20 mV recorded in the same cell. Represented in panel F are the averaged normalized window current traces at the potential range between −80 and +10 mV.
A ventricular pacemaker was implanted and atrioventricular node ablation was performed resulting in temporary atrioventricular block. During follow-up, the patient experienced a syncopal spell 3 times. A month later, sudden cardiac arrest occurred at home during stressful conditions; patient was resuscitated from ventricular fibrillation but died few days later.

Additionally, we repeated ETs to all family members (n=21, including both mutation carriers and family members not carrying the Nav1.5 p.I141V mutation) whose ET was normal at the first examination. In the follow-up test, 3 individuals (V-7, III-11, and II-7) showed ≥50 PVCs at the age of 31, 45, and 69 years, respectively. They were all carrying the Na_1.5 p.I141V mutation.

The ambulatory 24-hour ECG recording was performed at the end of follow-up period in 14 Na_1.5 p.I141V mutation carriers to assess the burden of AF. This revealed 1 additional patient (II:14) with AF, which would not have been diagnosed during ETs. At resting heart rates, PVCs were absent or their frequency was low in most Nav1.5 p.I141V mutation carriers but their incidence increased concomitantly with physical activity and increasing sinus rate as illustrated in Figure III in the Data Supplement.

Figure 4. Effects of the p.I141V mutation on I_{Na} properties, excitability, and conduction velocity in the human atrial (CRN [Courtemanche–Ramirez–Nattel]), the ventricular (TNNP [Tusscher–Noble–Noble–Panfilov]), and the Stewart–Aslanidi–Noble–Noble–Boyett–Zhang (SANNBZ) models. A–C, Steady state activation (m_3) and inactivation curves (h_j) in the CRN model (LR-CRN I_{Na} formulation; A), the TNNP model (B), and the SANNBZ model (C). D–F, Strength–duration curves in the CRN atrial cell model (inset, zoom on the strength–duration curves; D), the TNNP ventricular cell model (inset, zoom of the strength–duration curves; E), and the SANNBZ Purkinje cell model (inset, spontaneous action potentials showing the acceleration of the spontaneous rhythm because of the p.I141V mutation; F) with WT, heterozygous (Het), and homozygous p.I141V genotypes (pacing rate 1 Hz and 2.5 Hz). G–I, Excitation thresholds at 2 ms stimulus duration in the CRN atrial AP model (G), the TNNP ventricular AP model (H), and the SANNBZ Purkinje AP model (I; pacing rate 1 Hz and 2.5 Hz). J–L, Conduction velocities in the atrial CRN model (J), the ventricular TNNP model (K), and the SANNBZ Purkinje model (L; pacing rate 1 Hz and 2.5 Hz). Strength–duration curves and conduction velocities could not be established at 1 Hz in the Purkinje model because of the accelerated spontaneous rhythm caused by the p.I141V mutation.
Discussion

In the present study, we describe a novel missense mutation in a highly conserved region of the SCN5A gene, which associates with an autosomal dominantly inherited arrhythmic phenotype in a large multigenerational Finnish family. This phenotype is characterized by exercise-induced polymorphic PVCs, bigeminy, and nonsustained polymorphic ventricular tachycardia in structurally normal hearts. Arrhythmias disappear after cessation of exercise.

The affected family members displayed widespread cardiac hyperexcitability features manifesting as increased sinus rate, atrial ectopic rhythm, and atrial and nodal tachyarrhythmias. In the current SCN5A-linked family, the propensity to atrial arrhythmias appeared to increase with age, resulting in paroxysmal and eventually chronic AF in many cases. Also, the number of ventricular complexes during exercise increased in some patients during follow-up, further supporting a progressive nature of the disorder. The earliest age of onset of ventricular arrhythmias among mutation carriers cannot be exactly determined using data from this single family. The youngest mutation carrier capable of performing an ET was 11 years. Underscoring the diagnostic challenge, this boy did not exert multiple polymorphic PVCs during the clinical ET, in spite of that, his 24-hour ambulatory ECG recording revealed 1210 PVCs associated with physical exercise. Even if it is clear that the p.I141V mutation is not fully penetrant, the penetrance of the PVC phenotype is high, reaching 81% when considering only adult mutation carriers.

Evidence for Na\(_{1.5}\) p.I141V Causality in Exercise-Induced Polymorphic Arrhythmias

Although sequencing 2 putative genes (RYR2 and CASQ2) in affected members of the current family failed to identify any coding mutations, whole exome sequencing revealed a previously unknown missense mutation in SCN5A, which cosegregated with the arrhythmic phenotype. The accumulated evidence strongly supports the assumption that this variant is indeed functional and causes arrhythmia in the family investigated. First, the SCN5A gene resides in the only chromosomal region showing complete cosegregation with the ventricular arrhythmia phenotype. Second, the identified mutation results in an amino acid change p.I141V of the Na\(_{1.5}\) protein, which in silico is predicted to be possibly damaging. Third, the mutation resides in a region of the SCN5A gene that is highly conserved between species and Na\(_{1.5}\) homologues. Fourth, patch-clamp experiments show that the introduction of the mutation causes hyperexcitability of the Na\(_{1.5}\) channels. Finally, computational analyses of \(I_{\text{Na}}\) and AP in single cells imply that the biological changes caused by the p.I141V mutation both include an acceleration of the spontaneous depolarization rate in the Purkinje cell model, which is similar to what was reported for a multifocal ectopic Purkinje-related premature contraction–linked p.R222Q mutation by Mann et al.\(^5\) and a reduction of the threshold for cardiac cell excitability.

Isocine in the position 141 of the Na\(_{1.5}\) protein is highly conserved, not only across species, but also between Na\(_{1.5}\) isoforms. Interestingly, Na\(_{1.4}\) p.I141V and Na\(_{1.7}\) p.I136V mutations, that are homologous to the Na\(_{1.5}\) p.I141V mutation, have also been associated with hyperexcitability-dependent inherited disorders, that is, with myotonia and erythromelalgia.\(^{17-19}\) Both these previously described mutations induce similar modifications of the biophysical properties of the sodium voltage gated channels as was observed for the Na\(_{1.5}\) p.I141V mutation in the current study.\(^{17,19}\) Taken together, these findings strongly support the pathogenicity of this novel SCN5A missense variant.

Gain-of-Function Mutations in Na\(_{1.5}\) and the Clinical Phenotypes

Gain-of-function mutations in Na\(_{1.5}\) have previously been associated with several hereditary forms of arrhythmia,\(^{20}\) but also with the more recently described multifocal ectopic Purkinje-related premature contraction with cardiomyopathy, that is linked to the presence of the p.R222Q mutation in Na\(_{1.5}\).\(^{2-4}\)

In the current study, the clinical phenotype, associating with the p.I141V mutation, was characterized by a distinct hyperexcitability without evidence of conduction abnormalities or QT interval prolongation. Although the p.I141V and the p.R222Q mutation both associate with atrial arrhythmias, the clinical characteristics of the individuals carrying the p.I141V mutation differ from the phenotype described in p.R222Q-carriers. Although exercise provoked ventricular arrhythmias in p.I141V-carriers, p.R222Q-carriers typically manifest arrhythmias at resting heart rates. Moreover, carriers of p.R222Q show frequent PVCs, with both left and right bundle-branch block patterns triggered from Purkinje fibers at low heart rates, but disappearance of PVCs during exercise, and dilated cardiomyopathy.\(^{21}\) In p.I141V mutation carriers, the burden of PVCs was much lower, which may explain why they did not display any abnormalities in ventricular structure or contractility.

In spite of the above described dissimilarities between the clinical phenotypes, the differences in the cellular phenotypes associating with the p.I141V and p.R222Q mutations were more subtle. Although the p.I141V mutation did not modify the voltage dependence of inactivation, it did shift the activation curve to negative potentials and led to an increase and shift of the sodium window current. In contrast, the p.R222Q mutation affects the voltage dependence of both activation and inactivation, resulting in a negative shift of the sodium window current. To bear in mind, in vitro phenotypes observed in heterologous expression systems may not always reflect the clinical phenotypes induced by a mutation. As an example, although many studies have reported several varied phenotypes associating with a SCN5A p.D1275N missense mutation, for example, atrial standstill, dilated cardiomyopathy with conduction disease, atrial flutter/fibrillation, sick sinus syndrome, and ventricular dilation and dysfunction, the mutation does not induce marked Na\(_{1.5}\) dysfunction in vitro. However, when studied in genetically engineered mice, in vivo, the mutation generates extensive aberration of channel function,\(^{21}\) underscoring that functional phenotypes may be influenced substantially by the experimental systems used.

Overall, the complex pathways underlying the genotype–phenotype relationship in hereditary arrhythmia syndromes are poorly known, and the reasons for incomplete penetrance and variable expressivity remain obscure.\(^{1,22}\) Pleiotropy has been associated with SCN5A mutations in particular. Although distinct clinical phenotypes have been ascribed to different mutations in the SCN5A gene, for example, LQTS, BrS, and cardiomyopathy by others and the present exercise-induced phenotype by us,\(^{23-29}\)
some mutations also display a substantial degree of variability within families. For example, the affected family members of a large family segregating a SCN5A-1795insD presented with a wide array of clinical manifestations, including sinus node dysfunction, bradycardia, conduction disease, BrS, and LQTS.3,23

Mechanistic Considerations
The mutation-induced alterations of Na,1.5 properties and simulation studies support the concept that the increase in window current lead to a ventricular and atrial hyperexcitability. It is interesting to note that administration of flecainide 2 mg/kg IV to patients II-10 and III-19 resulted in a significant reduction of PVCs during an exercise stress (from 219 and 540 to 17 and 0, respectively). Also, in a previous study, flecainide has been shown to induce a dramatic reduction in PVCs and recovery of normal left ventricular function in respectively). Also, in a previous study, flecainide has been shown to induce a dramatic reduction in PVCs and recovery of normal left ventricular function in (respectively). Also, in a previous study, flecainide has been shown to induce a dramatic reduction in PVCs and recovery of normal left ventricular function in

Although flecainide may directly act on RyR2 channels,30–32 it has recently been suggested that the drug may reduce sodium channel availability, which would increase the channel threshold for triggered activity.33 Recently, using a rat cardiomyocyte model, Sikkel et al showed that flecainide reduces calcium sparks by a mechanism involving reduction of Ica, that is, through increased Ca2+ efflux via the sodium–calcium exchanger across the sarcolemma and reduced Ca2+ concentration in the vicinity of the RyR2. Given these previous observations linking Ica with calcium homeostasis, one may speculate that the mechanism whereby the SCN5A p.I141V may cause exercise-induced PVCs in part may involve alterations of intracellular calcium flux.

Conclusions
The Na,1.5 protein, encoded by the SCN5A gene, has previously been associated with a variety of clinical arrhythmia phenotypes, including congenital LQTS, BrS, and multifocal ectopic Purkinje-related premature contraction. The present study demonstrates that mutations in SCN5A also may result in exercise-induced polymorphic ventricular premature complexes and tachycardia.

Acknowledgments
We thank Hanna Ranne, Minna Härkönen, and Jouko Siro for their excellent technical assistance. The whole exome sequencing and whole-genome linkage analyses were carried out at the Technology Center at the Institute for Molecular Medicine Finland, Helsinki, Finland.

Sources of Funding
This study has been supported by grants from the Finnish Foundation for Cardiovascular Research, Helsinki, Finland, the Sigrid Juselius Foundation, Finska Läkareällskapet, and the Swiss National Science Foundation to H. Abriel (310030 120707).

CLINICAL PERSPECTIVE

Premature ventricular complexes constitute a diagnostic challenge because in a small proportion of patients, they may indicate the risk of lethal ventricular tachycardia or fibrillation. Exercise-induced premature ventricular complexes, bigeminy, and ventricular tachycardias in structurally normal hearts are characteristic of the catecholaminergic polymorphic ventricular tachycardia and are associated with considerable mortality. A correct presymptomatic diagnosis by genetic testing is particularly valuable because lethal arrhythmias may occur in catecholaminergic polymorphic ventricular tachycardia even before diagnostic exercise-induced symptoms can be verified, at least in carriers with mutations of the ryanodine receptor type 2 gene. We demonstrate in this investigation that a mutation in the cardiac sodium channel gene SCN5A can also cause exercise-induced polymorphic ventricular tachycardias. Similar to catecholaminergic polymorphic ventricular tachycardia, physical exercise provokes premature ventricular complexes and nonsustained polymorphic ventricular tachycardia that disappear after cessation of exercise. Unlike in catecholaminergic polymorphic ventricular tachycardia, also the atria are prone to ectopic activity and tachyarrhythmias. Our findings could help the clinician to differentiate these exercise-provoked ventricular arrhythmias from those associated with ryanodine receptor type 2 and calsequestrin 2 mutations. Awareness of the potential contribution of SCN5A to inherited exercise-induced polymorphic ventricular tachyarrhythmias could facilitate the identification of more mutation carriers and assist in determining their prognostic significance. Patients with the exercise-induced polymorphic ventricular arrhythmias could be tested also for the SCN5A gene, particularly if ryanodine receptor type 2 and calsequestrin 2 have tested negative. In general, the present study demonstrates the importance of genotypic and phenotypic classification of cardiac arrhythmias which have similar clinical presentations but actually may have different prognosis and require different therapeutic approaches.
