This work was presented at the 99th Annual Congress of the Swiss Society of Surgery, Davos, Switzerland, 20–22 June 2012.
Abstract

Purpose: Reliable animal models are essential to evaluate future therapeutic options like cell-based therapies for external anal sphincter insufficiency. The goal of our study was to describe the most reliable model for external sphincter muscle insufficiency by comparing three different methods to create sphincter muscle damage.

Methods: In an experimental animal study female Lewis rats (200–250 g) were randomly assigned to three treatment groups (n=5, each group). The external sphincter muscle was weakened in the left dorsal quadrant by microsurgical excision, cryosurgery, or electrocoagulation by diathermy. Functional evaluation included in vivo measurements of resting pressure, spontaneous muscle contraction, and contraction in response to electrical stimulation of the afferent nerve at baseline and at 2, 4, and 6 weeks after sphincter injury. Mason trichrome staining and immunofluorescence for skeletal muscle markers was performed for morphological analysis.

Results: Peak contraction after electrical stimulation was significantly decreased after sphincter injury in all groups. Contraction forces recovered partially after cryosurgery and electrocoagulation but not after microsurgical excision. Morphological analysis revealed an incomplete destruction of the external sphincter muscle in the cryosurgery and electrocoagulation groups compared to the microsurgery group.

Conclusions: For the first time three different models of external sphincter muscle insufficiency were directly compared. The animal model using microsurgical sphincter destruction offers the highest level of consistency regarding tissue damage and sphincter insufficiency, and therefore represents the most reliable model to evaluate future therapeutic options. In addition this study represents a novel model to specifically test external sphincter muscle function.

Key words: anal incontinence, animal model, external sphincter, microsurgery
Introduction

Fecal incontinence limits daily activities and strongly influences the patient’s psychological, emotional, and social wellbeing.[1,2] The high prevalence[3,4,2] and the significant socio-economic impact of the disease on one hand[5] and the limitations of current therapeutic options especially for large defects of the external sphincter on the other hand highlight the importance of ongoing research in the field.[6-8]

Research concentrates on the external sphincter for several reasons: This part of the sphincter muscle is much more voluminous in humans in comparison to the internal sphincter muscle and is frequently affected after obstetric traumas.[9,10] The external sphincter is relevant in preventing urge incontinence[11,12] and contributes to the maintenance of passive continence.[13]

However, in previous studies, a variety of methods including sphincterotomy[14,15], resection of the internal and external sphincter[16], electrocoagulation[17] or cryo-injury[18] to generate models for sphincter muscle insufficiency have been used. Therefore data comparison across the literature is difficult.

Beside creation of a distinct defect of the external sphincter this muscle has to be accessible to functional evaluation in order to test new therapeutic procedures. In vivo measurement of the resting pressure has been described previously.[19,15] However, since the resting pressure is generated by the internal and external sphincter[13] this examination allows no individual functional evaluation of both muscles. A rat animal model that permits assessment of squeeze pressure to specifically evaluate the external sphincter muscle does not exist so far.
This study was designed to describe a rodent animal model with a consistent, isolated
defect of the external sphincter, which offers functional in vivo evaluation of this muscle.

We therefore compared three different techniques of isolated and irreversible external
sphincter injury including microsurgical excision, which has not been described before,
cryosurgery and electrocoagulation.
Materials and methods

Study design and protocol

The study was performed with the approval of the Animal Care Committee of the Canton of Zurich, Switzerland. Preliminary experiments were conducted to determine the optimal settings for the in vivo assessment of sphincter function. These experiments included evaluation of the most precise localization for electrical nerve stimulation to induce external sphincter muscle contraction.

For the final evaluation, a total of 15 adult female Lewis rats (200–250 g) were randomly placed into three groups (n=5, each group) for functional analysis. Another 6 animals served for morphological investigations. Baseline manometric assessment included resting pressure, spontaneous contractions, and contractions in response to electrical stimulation.

As shown in Figure 1, the left dorsal quadrant of the external sphincter muscle was microsurgically removed (MS group) or destroyed by cryosurgery (CS group) or electrocoagulation using diathermy (EC group). Manometric evaluation was repeated at 2, 4, and 6 weeks after sphincter damage. Additionally, after 2 and 4 weeks one animal and after 6 weeks four animals per group were sacrificed for tissue retrieval and histological analysis. Samples from the untreated right-dorsal quadrant served as internal controls.

Animal anesthesia and surgery

All animals received Caprofen (Rimadyl®, Pfizer AG, Zürich, Switzerland; 5mg/kg bodyweight) and Buprenorphine (Temgesic®, Reckitt Benckiser AG, Wallisellen, Switzerland; 0.01-0.05 mg/kg bodyweight) by subcutaneous injection 30 minutes prior to
surgery. Anesthesia was induced by inhalation of 5% isoflurane and maintained using 1–2% isoflurane. The surgical area was shaved and disinfected with povidone-iodine solution. After a left circum-anal incision the fat was separated from the lower rectum and anal canal under an operating microscope and the left dorso-lateral quadrant of the sphincter muscle was exposed.

For partial sphincter damage, approximately 25% of the circumferential external sphincter muscle fibers were removed or destroyed. Before microsurgical excision the external sphincter muscle was separated from the underlying internal sphincter muscle. Cryosurgery of the anal sphincter was induced in anesthetized rats using an aluminum rod measuring 2 × 5 mm, which was chilled in liquid nitrogen as was previously described.[18] The chilled probe was held towards the anal sphincter for 15 seconds. Sphincter injury by electrocoagulation was induced with the use of an electrical surgical bipolar forceps, similar to a technique used for urinary sphincter injury.[17] Electrocoagulation of the left-dorsal external sphincter muscle was performed on an area of 5 × 2 mm for 1 second.

Resorbable suture material was used for skin closure.

After surgery observations were made every 15 minutes until the animals were fully awake and active. Thereafter, animals were returned to their normal housing. Caprofen (5 mg/kg bodyweight once daily) and Buprenorphine (0.01–0.05 mg/kg bodyweight twice daily) were administered subcutaneously for 48 hours. Animals were carefully monitored for signs of infection.
Anal manometric evaluation

All examinations were done under general anesthesia in the supine position. Based on previous studies[19,15] we used a saline-filled latex balloon connected through PE-100 tubing to a pressure transducer (SP 844, Memscap, Crolles Cedex, France) and a digital data acquisition system (Powerlab 4/35 with LabChart Pro, ADInstruments, Spechbach, Germany) for anal manometric measurements. After the balloon was inflated to 10 cm H2O and pressure calibration of the system was accomplished. After adaption of 15 to 30 minutes, spontaneous contraction waves were recorded for 5 minutes. The peak contraction, area under the curve (AUC), and frequency of the contraction waves were recorded (Fig. 2A). To determine the resting pressure, the balloon probe was drawn out in a contraction interval and the resulting difference to the baseline pressure (mean of 5 intervals) calculated. For the assessment of sphincter contraction after electrical stimulation of the inferior rectal nerve, a bipolar electrode was inserted through a 2-mm incision at the ventral verge of the anus. We used a Grass S48 Stimulator (Grass Technologies, Astro-Med, Rodgau, Germany) at 30 Hz (pulse duration 1ms), 30 V for 2 seconds for the electrical stimulation. The best stimulation location was defined as the place with minimal leg twitching and maximal sphincter response. The peak contraction force and the maximal slope of the contraction waves were registered (Figure 2B). An average of five contractions was used for statistical analysis.

Histology and immunohistochemistry

Animals were sacrificed under anesthesia by thoracotomy and incision of the heart. After a circum-anal incision the anus and lower rectum were removed en-bloc. The total specimen
was fixed in formalin for 24 hours and rinsed in phosphate buffered saline. After
dehydrating overnight in a histokinette (Tissue Processor TP 1020, Leica Microsystems,
Wetzlar, Germany) the samples were embedded in paraffin.

The blocks were sectioned into 3-μm slices using a microtome (Model RM 2155, Leica
Microsystems, Wetzlar, Germany). The sections were fixed and labeled with Mason’s
trichrome stain. Sphincter muscle cells were identified via immunocytochemistry using an
anti-α-actinin antibody (Sigma-Aldrich, Buchs, Switzerland) at a dilution of 1:100. Native
sphincter tissue sections served as positive controls. Tissue sections without primary
antibody were used as negative controls. Alpha-actinin labeled cells were identified by
fluorescence microscopy (Leica DM 6000 B / DFC 350 FX, Leica Microsystems, Wetzlar,
Germany) using an excitation wavelength of 550 nm. Nuclei were stained with DAPI (4',6-
diamidino-2-phenylindole; Sigma-Aldrich, Buchs, Switzerland). Image analysis to
determine signal intensity per high power field was performed (ImageJ 1.45s, Wayne
Rasband, National Institutes of Health, Bethesda MD, USA).

Statistical analysis

All experimental groups contained five animals for functional analysis at each time-point.
The presented data are expressed as averages ± the corresponding standard error of the
mean. The repeated measures analysis of variance (ANOVA) was performed to assess the
group effect for quantitative variables. The Bonferroni pairwise multiple comparison test
was used to compare measurements after the intervention with the baseline values within
the groups (time effect). Measurements at the end of the experiment were compared with
unpaired students t-tests. All tests were performed bilaterally with a 5% significance
threshold. The NCSS/PASS software package (NCSS, Kaysville, UT, USA) was used for all calculations.
Results

No intraoperative or postoperative complications occurred in either group. In particular, no rectal perforation, anal stricture or wound infection occurred.

**Manometric evaluation during electrical nerve stimulation**

Peak contractions were significantly reduced in all groups after model generation when compared to normal pressures (MS: 6.7±1.9 cmH2O vs 25.7±2.1cmH2O; EC: 7.9±1.8cmH2O vs 26.2±2.8 cmH2O; CS: 6.6±1.8 cmH2O vs 26.5±0.7 cmH2O). Peak contraction pressures were only reduced after cryosurgery and microsurgery over all time-points investigated as is demonstrated in Figure 3A. However, the values after microsurgery were significantly lower. The slope of the contraction waves recovered over time after sphincter damage by cryosurgery and electrocoagulation (Fig. 3B). The values in the microsurgery group were significantly lower for peak pressures (MS: 6.2 ± 1.1 cm H2O; EC 13.8 ± 2.2 cm H2O; CS 15.8 ± 2.2 cm H2O) and slope of the contraction waves (MS: 18.4 ± 2.5 cm H2O/sec; EC 33.5 ± 7.4 cm H2O/sec; CS 39.2 ± 5.4 cm H2O/sec) compared to the other groups at the end of the experiment (6 weeks after model generation).

**Spontaneous manometric evaluation**

Spontaneous, rhythmic contraction waves of the sphincter muscles demonstrated great variability between time-points and animals (Fig. 4). Peak contraction, area under the
curve (impulse), frequency, and resting pressures did not differ from baseline values or between the groups. Resting pressures demonstrated a trend toward temporary recovery after 2 and 4 weeks, respectively (Fig. 4D).

Histology and immunohistochemistry

The external sphincter muscle was consistently removed at all time points after microsurgery (Fig. 5A-D). After cryosurgery and diathermy skeletal musculature from the external sphincter muscle was partially recognizable at all time points (Fig. 5F-H and J-L). No significant inflammatory reaction was registered at later time points.

A sustained loss of muscle tissue in the MS group (28.0 ± 4.9 pixels × 10^3/high power field 6 weeks after model generation) compared to the control group (462.9 ± 28.4 pixels × 10^3/high power field) was demonstrated in immunofluorescence analysis using α-actinin as a specific musculoskeletal marker (Fig. 6B-D, M). Reduction of α-actinin expression was less pronounced in the EC and CS groups, showing values of 143.4 ± 8.3 and 204.8 ± 9.2 pixels × 10^3/high power field, respectively (Fig. 6H, L, M).
Discussion

In this study, three rat animal models for the evaluation of the external anal sphincter function have been explored. The results from this study objectively reveal functional and morphological regeneration after cryosurgery and electrocoagulation after 6 weeks, which was not found after microsurgical excision.

The advantage of microsurgery seems to be that skeletal muscle tissue can be removed under direct visual control until no muscle fibers are left. On the other hand, after cryosurgery and electrocoagulation necrotic tissue remains, and the depth of the injury cannot be precisely controlled. Thus, potentially vital skeletal muscle fibers remain underneath or in the necrotic area and repair mechanisms based on satellite cells might help to quickly regenerate muscular tissue.[20] In order to prevent such a mechanism the interval and intensity of cryosurgery or electrocoagulation must be increased. However, individual anatomical differences and lacking possibilities to control the depth of penetration increase the risk to go beyond the target by destroying the adjacent internal sphincter muscle.

We did not observe any changes at the different time points or between models after either method of external sphincter destruction for frequency, peak force, and impulse (area under curve) of spontaneous contraction waves in the anal canal. These results support the current understanding that these spontaneous contraction waves are provoked by contractions of the internal sphincter,[13] which was not intended to be damaged in our model. Involvement of the internal sphincter using cryosurgery and electrocoagulation is possible since the depth of destruction with these methods is more difficult to control. Therefore differences between models during spontaneous contractions may be detected with a larger sample size. However, since our model was developed for external sphincter
assessment our experiments were not designed to find differences in spontaneous contractions, which are related to internal sphincter function.

After destruction of the external sphincter a significant impairment of the resting pressure would be expected.[13] Conversely, only a non-significant reduction of sphincter pressure could be demonstrated in all groups. This might be due to a distinct anatomical difference between humans and rats, among which the external sphincter is less voluminous. With regard to the resting pressure, it seems that in rats the internal sphincter can compensate the damaged external sphincter. Moreover, a transient trend towards recovery of the resting pressure with a peak after 2 and 4 weeks might be explained by postoperative edema.

Indeed, the ratio of thickness between internal and external sphincter muscle in rats is not exactly comparable to humans. This fact does not signify a limitation of the present study since this model was specifically developed to study damage of the external sphincter muscle. This muscle can be selectively assessed for functional and morphological analysis, which underlines the relevance of this model. Selective assessment of the external sphincter has been described in larger animals[21], such as rabbits or dogs. Compared to these experiments our rat model seems to provide similar possibilities of external sphincter evaluation in the lowest possible species. One of the main restrictions of our model is the translation of the resting pressure measurements to humans. However, resting pressure is always a product of internal and to a minor part of external sphincter muscle function[13] and is therefore not suitable for external sphincter assessment.

A limitation of this study might further be represented by the very critical exact position of the probe for electrical stimulation of the afferent nerve for muscle contraction. In order do encounter this potential bias, the best stimulation location was defined as the place with
minimal leg twitching and maximal sphincter response. An average of five contractions was then used for statistical analysis.

Our study has a number of important strengths. First, a reliable animal model facilitates both evaluation of novel therapy options and physiological studies of underlying mechanisms. By comparing different methods of sphincter destruction this study represents an important landmark to encounter efforts for standardization and rationalization of animal models and evaluation methods for studying the anal sphincter.

Second, with regard to testing of future therapy options including cell-based therapies\[22,18,14\] or tissue engineering\[23\] for external sphincter muscle regeneration we chose to induce sustained long-term external sphincter muscle damage. Previous studies evaluating such therapies were based on animal models with destruction of both sphincter muscles.\[22,18,14\] Still, in such a model function of one muscle might be influenced by the destruction of the other muscle, which complicates interpretation of outcome measures. Our animal model presented in this study consists of an isolated defect of the external sphincter and will therefore allow unbiased evaluation of this muscle.

Third, with this study we describe a method to selectively assess external sphincter function of rats \emph{in vivo} by electrical stimulation of the inferior rectal nerve and balloon manometry. Functional evaluation of the external sphincter muscle was performed so far \emph{ex vivo} using organ bath studies.\[18,14\]. However, conclusions from a denervated piece of muscle, which is isolated from its surroundings on \emph{in vivo} function, have consequently to be drawn with caution.

In conclusion, this study presents, a rodent animal model offering a morphologically well-defined external sphincter muscle defect, which is mirrored in a corresponding loss of
contraction force. For that purpose a novel method to specifically assess external sphincter function in rats was described. The objective analysis of three distinct methods for creating a model of external sphincter muscle insufficiency provides evidence that sphincter destruction by microsurgery represents the most reliable model in terms of persisting morphological and functional deficiency compared to cryosurgery and electrocoagulation. Therefore, this animal model should be considered when evaluating novel therapeutic options for external sphincter muscle defects.
