Southern South America, the only landmass between 38°S and the Antarctic Circle, offers a unique opportunity to reconstruct terrestrial paleoclimates in an area affected by shifts of polar and mid-latitude wind and pressure fields. It is one of the key regions suited to a better understanding of long- and short-term climate processes, supporting one of the major DEKLIM goals i.e. to improve climate predictability at global and regional scales. The Antarctic Circumpolar Current advecting cold air to the continent is a major factor controlling the climatic conditions of Patagonia. The DEKLIM project “South Argentine Lake Sediment Archives and Modeling” (www.SALSA.uni-bremen.de) investigates lacustrine sediments with an integrated research strategy to understand ecosystem changes in space and time. In conjunction with results from DEKLIM-RESPIC, which studies ice cores from the EPICA drill site in Antarctica, new keys to the understanding of southern ocean atmosphere variability can be expected.

SALSA studies are carried out in the Pali Aike Volcanic Field (PAVF; Santa Cruz province, southern Patagonia, Argentina). The PAVF covers an area of 4500 km² and is located west of the city of Río Gallegos, immediately north of the Strait of Magellan (Fig. 1). Volcanism is characterized by plateau-like lava flows with eruption dates between 0.17 and 3.78 Ma BP (Corbella, 2002), scoria cones and maars. A few maar-like structures contain permanent lakes varying from 500 to 3700 m in diameter and exhibiting up to 100 m water depth. The PAVF was not covered by Andean piedmont glaciers during the last glaciations. Thus, it is likely that long, continuous, continental paleoenvironmental and paleoclimatic records covering several glacial and interglacial cycles might be preserved in these volcanic lakes, which could be drilled in the framework of the International Continental Drilling Programme (ICDP). This would trigger a close cooperation with DEKLIM-EEM because it opens the possibility to study high resolution records of the same age and from the same depositional environment (maar lakes).

As a first spin-off from the two cooperating DEKLIM projects SALSA and PROSIMUL, the project MIDHOL was launched in 2004. It aims to improve the understanding of climate variability in the time window 4500–6500 years BP by running a transient simulation with a coupled atmosphere-ocean General Circulation Model.

Environmental Setting

The climate of south-eastern Patagonia is determined by the southern westerlies and the rain shadow of the Andes. Both factors lead to a dry continental climate with a strong precipitation gradient from 410 mm of annual precipitation in the west (Río Turbio at the eastern foot of the Andes) to less than 150 mm at Laguna Potrok Aike in the PAVF. This precipitation gradient is crucial for vegetation patterns. The PAVF is covered by steppe vegetation of a moister type occurring mainly near the Andes and a drier type that occurs in the central and eastern parts of Santa Cruz and which dominates around the investigated lakes, Laguna Potrok Aike (supposedly a maar lake) and Laguna Azul (a crater lake). Nowadays, this vegetation...
is strongly altered by sheep farming that commenced during the late 19th century.

The lakes exhibit very different limnological characteristics (Zolitschka et al., submitted). For instance, Laguna Potrok Aike is relatively large (diameter 3700 m, water depth 100 m) and exposed to strong winds. With a specific conductivity of 3000 µS/cm and an alkalinity of 13 meq/l, Laguna Potrok Aike is classified as a hardwater lake with a relatively high ionic concentration. In contrast, Laguna Azul is smaller (diameter 560 m, water depth 56 m) and wind protected by steep crater walls. Sediment records and morphology of the crater indicate a rather young (mid-Holocene) age for Laguna Azul. Specific conductivity and alkalinity of the lake water are rather low (440 µS/cm, 4 meq/l), pointing to different evaporation conditions at Laguna Azul compared to Laguna Potrok Aike.

**Sediments**

Gravity cores (up to 130 cm in length) from Laguna Potrok Aike and Laguna Azul have been studied. An integration of sedimentary parameters and dating (SALSA I), volcanic history (H. Corbella), fossil pollen (SALSA II), diatoms (N. Maidana), actual pollen rain (M. Paez), actual vegetation (INTA, Rio Gallegos), limnological and stable isotope (SALSA III) analyses yields the first multi-proxy palaeoenvironmental reconstruction for this area. 22 AMS radiocarbon dates provide a chronological framework and indicate that the analyzed records of Laguna Potrok Aike (100 cm, 13 dates) and Laguna Azul (130 cm, 9 dates) cover the last 1600 and 1300 years, respectively. The palynological records of both lakes are dominated by pollen of regional Patagonian steppe taxa. However, a high amount of Andean forest taxa is remarkable, as the tree-line today is situated ca. 120 km west of Laguna Azul and ca. 60 km west of Laguna Potrok Aike. Although the limnological settings of the two lakes are different, there are indications that their sediments record similar environmental changes related to climate variability and human activities.

**Laguna Azul**

High concentrations of biogenic silica and C/N ratios <9 in the sediments confirm a planktonic origin of sediment organic matter. Both parameters are strongly correlated with pollen concentrations of Patagonian steppe taxa. An interpretation integrating the data from Laguna Azul suggests that the climate became cooler after AD 1480 compared to a warmer interval between the 11th and 15th century (Mayr et al., submitted). In Figure 2, the δ13C-profile is shown as an example of lacustrine paleoproductivity. Cool climate conditions culminated around AD 1560 and prevailed until the end of the 16th century. Despite a climatic amelioration in the 17th and 18th century, it remained cool until the start of the 20th century. Since the middle of the 20th century, proxies have shown a warming trend that caused the lake level to drop.

**Laguna Potrok Aike**

The calcite content in the sediment of Laguna Potrok Aike (Fig. 1) serves as a proxy for lake level changes (Fig. 2). Lake internal calcite precipitation depends on the ion concentrations in the lake water and thus reflects regional hydrological variations. The succession of moist/dry phases inferred from calcite-variations is supported by δ13C, δ18O and C/N ratios (Haberzettl et al., submitted). Changes in these parameters represent varying input of the remains of water plants transported from shallow water habitats to the lake center and thus may also provide information about the lake level history. Between the 5th and 11th century, relatively frequent moist/dry fluctuations were noticed. Between the 11th and 20th century, conditions were relatively moist except for a dry period between the 13th and 15th century. The change from dry to moister conditions was dated to the 15th century. Since the middle of the 20th century, climate has been characterized by increasing drought.

**European Impact**

It has been one of the most important influences on South Patagonian ecosystems during the last centuries. The arrival of European sheep farmers at the end of the 19th century initiated several feedback mechanisms leading to the degra-
Azul probably dates back to ca. 4500 cal. y BP, whereas Laguna Potrok Aike offers the potential for a much longer record. Seismic surveys carried out with a 3.5 kHz system in 2003 and with an airgun system in 2004 demonstrate the presence of more than 30 to 40 m of undisturbed pelagic lake sediments. Continuous seismic reflections of the pelagic sediments are cut by steep crater slopes (Fig. 3). The seismic survey showed a topographic shoulder in the upper part of the slope. Here seismic data display a highly reflective pattern and a maximum penetration of around 15 m. An erosional unconformity, marked as blue horizon in Figure 3, persistently occurs around the entire lake cutting reflections of the underlying upper slope sections. The consistent water depth of the outcrop of the unconformity points to an ancient shore line formed by a lake level lowering of about 35 m. On the other hand, terraces formed by wave action exposed up to 19 m above the present shore line point to periods with much higher lake levels in the past than today.

Physical properties (magnetic susceptibility, GRAPE density) measured for two cores (PTA 03/5, PTA 03/6) taken above and below the erosional unconformity (Fig. 3) display different sediment types. Additionally, the latter cannot be correlated to sediments from the central basin (PTA 03/12). Therefore, it is likely that these sediments were deposited in an earlier lake phase and are older than the strata recovered with the 18.9 m piston core from the central basin.

SALSA is scheduled for another two years in which the already taken long cores will be analyzed. Continuous sediment cores of 6.5 m from Laguna Azul and 18.9 m from Laguna Potrok Aike provide a promising source of information for the reconstruction of the Holocene and Late Glacial climate history of southernmost South America within the framework of DEKLIM. Furthermore, a seismic survey with a stronger acoustic source carried out in February 2004 clarified that the sediment infill of Laguna Potrok Aike exceeds 40 m. Thus, Laguna Potrok Aike will be suggested as a target site for ICDP.

**Sediment Records**

Examination of the sediment records from Laguna Potrok Aike and Laguna Azul has made possible the first reconstruction of regional paleoenvironmental history dating back to AD 800. Both records indicate that a major climate change from warm/dry conditions to cool/wet conditions occurred during the 15th century (Fig. 2). Since the middle of the 20th century, the climate has been warmer and drier. Human impact is documented for two phases, at the end of the 16th and at the end of the 19th centuries.

**Perspectives**

The sediment record of Laguna Azul probably dates back to ca. 4500 cal. y BP, whereas Laguna Potrok Aike offers the potential for a much longer record. Seismic surveys carried out with a 3.5 kHz system in 2003 and with an airgun system in 2004 demonstrate the presence of more than 30 to 40 m of undisturbed pelagic lake sediments. Continuous seismic reflections of the pelagic sediments are cut by steep crater slopes (Fig. 3). The seismic survey showed a topographic shoulder in the upper part of the slope. Here seismic data display a highly reflective pattern and a maximum penetration of around 15 m. An erosional unconformity, marked as blue horizon in Figure 3, persistently occurs around the entire lake cutting reflections of the underlying upper slope sections. The consistent water depth of the outcrop of the unconformity points to an ancient shore line formed by a lake level lowering of about 35 m. On the other hand, terraces formed by wave action exposed up to 19 m above the present shore line point to periods with much higher lake levels in the past than today.

Physical properties (magnetic susceptibility, GRAPE density) measured for two cores (PTA 03/5, PTA 03/6) taken above and below the erosional unconformity (Fig. 3) display different sediment types. Additionally, the latter cannot be correlated to sediments from the central basin (PTA 03/12). Therefore, it is likely that these sediments were deposited in an earlier lake phase and are older than the strata recovered with the 18.9 m piston core from the central basin.

SALSA is scheduled for another two years in which the already taken long cores will be analyzed. Continuous sediment cores of 6.5 m from Laguna Azul and 18.9 m from Laguna Potrok Aike provide a promising source of information for the reconstruction of the Holocene and Late Glacial climate history of southernmost South America within the framework of DEKLIM. Furthermore, a seismic survey with a stronger acoustic source carried out in February 2004 clarified that the sediment infill of Laguna Potrok Aike exceeds 40 m. Thus, Laguna Potrok Aike will be suggested as a target site for ICDP.
