26 **ABSTRACT**

27 Serotype 19A strains have emerged as a cause of invasive pneumococcal disease after the  
28 introduction of the seven-valent pneumococcal conjugate vaccine (PCV7) and serotype 19A  
29 has now been included in the recent thirteen-valent vaccine (PCV13). Genetic analysis has  
30 revealed at least three different capsular serotype 19A subtypes and nutritional environment  
31 dependent variation of the 19A capsule structure has been reported. Pneumococcal vaccine  
32 effectiveness and serotyping accuracy might be impaired by structural differences in  
33 serotype 19A capsules. We therefore analyzed the distribution of 19A subtypes collected  
34 within a Swiss national surveillance program and determined capsule composition in  
35 different nutritional conditions with high-performance liquid chromatography (HPLC), gas  
36 chromatography – mass spectrometry (GC-MS) and nuclear magnetic resonance  
37 spectroscopy (NMR). After the introduction of PCV7 a significant relative increase of subtype  
38 19A-II and decrease of 19A-I occurred. Chemical analyses showed no difference in the  
39 composition as well as the linkage of 19A subtype capsular saccharides grown in defined  
40 and undefined growth media being consistent with a trisaccharide repeat unit composed of  
41 rhamnose, N-acetyl-mannosamine and glucose. In summary, our study suggests that no  
42 structural variance dependent of the nutritional environment or the subtype exists. The  
43 serotype 19A subtype shift observed after the introduction of the PCV7 can therefore not be  
44 explained by selection of a capsule variant. However, capsule composition analysis of  
45 emerging 19A clones is recommended in cases where there is no other explanation for a  
46 selective advantage such as antibiotic resistance or loss or acquisition of other virulence  
47 factors

48

49 **INTRODUCTION**

50 The polysaccharide capsule is a major virulence factor of the human pathogen  
51 *Streptococcus pneumoniae* (pneumococcus) and more than 90 different capsular types are  
52 known today, which differ in the chemical structure of their capsular polysaccharides (1).

53 These differences are reflected in the type-specific reaction with anticapsular antibodies, by  
54 which a serotype is determined and cross-reactive serotypes are pooled into serogroups.

55 The serogroup 19 contains, among others, serotypes 19F and 19A, which belong to the  
56 clinically most relevant serotypes (2). Based on both genetic background and chemical  
57 analyses the serotype 19A and 19F oligosaccharide repeating unit structures have been  
58 determined to be trisaccharides of glucose (Glc), rhamnose (Rha) and N-acetyl-  
59 mannosamine (ManNAc), differing only in the glycosidic linkage between glucose and  
60 rhamnose:

61 19F:  $\rightarrow 2)\text{-}\alpha\text{-L-Rha-(1}\rightarrow\text{PO}_4\rightarrow 4)\text{-}\beta\text{-D-ManNAc-(1}\rightarrow 4)\text{-}\alpha\text{-D-Glc-(1}\rightarrow$

62 19A:  $\rightarrow 3)\text{-}\alpha\text{-L-Rha-(1}\rightarrow\text{PO}_4\rightarrow 4)\text{-}\beta\text{-D-ManNAc-(1}\rightarrow 4)\text{-}\alpha\text{-D-Glc-(1}\rightarrow (1, 3\text{-}5)$ .

63 Based on chemical analyses two types of 19A oligosaccharide structures have been  
64 described (6, 7). In addition to the genetically proposed structure above, an alternative with a  
65 serotype 19F backbone and two side chains of  $\beta\text{-D-GlcNAc-(1}\rightarrow 3)\text{-}\beta\text{-D-Gal- (1}\rightarrow\text{P}\rightarrow 2)$  and  
66  $\alpha\text{-L-Fuc-(1}\rightarrow\text{P}\rightarrow 3)$  has been reported based on chemical analysis (7). The polysaccharide  
67 structures appear to vary with different *in vitro* growth conditions (6). Influence of the  
68 nutritional environment on the pneumococcal polysaccharide capsule could have biological  
69 consequences, as this would potentially impair any intervention or test targeting the  
70 pneumococcal capsule. For example, the fungus *Cryptococcus neoformans* is known to be  
71 able to change the capsule structure *in vitro* and also during infection (8-11), and those  
72 changes have been shown to lead to altered antigenicity (8, 11).

73 Because polysaccharides for pneumococcal vaccine production are derived from *in vitro*  
74 cultures, a nutrient-dependent variation could lead to antigenic preparations which differ from  
75 the *in vivo* antigen.

76 Capsule variation could also impair diagnostic procedures such as classical serotyping,  
77 which is based on polysaccharide specific antigen-antibody reaction.

78 Serotype 19A strains have emerged after the introduction of the seven-valent pneumococcal  
79 vaccine, and were subsequently included in the thirteen-valent vaccine now recommended  
80 in most countries (12, 13). The emergence of serotype 19A after the introduction of the  
81 seven-valent vaccine was surprising, as a cross-protection was expected due to close  
82 chemical similarity to the serotype 19F capsule as it was observed for serotypes 6A and 6B  
83 which also differ only by one glycosidic linkage (14, 15). Furthermore, 19F-19A cross-  
84 protection had been observed to a certain degree in an animal model (16). Recent work  
85 suggests a conformational difference in polysaccharide structure, which might explain the  
86 reduced cross-protection (17, 18).

87 At least three different 19A capsule subtypes are known based on the genetic arrangement  
88 of the capsule gene locus compared to a reference strain (19). In addition to various SNPs  
89 along the capsule operon, most characteristically, subtypes I and II have an inverted *rmID*  
90 gene, which is the last gene in the rhamnose synthesis pathway (3). To our knowledge, no  
91 variations in the capsule structure have been described for different subtypes.

92 Given the recent discovery of 19A capsular subtypes and previous reports of structural  
93 variants as well as the introduction of serotype 19A in the 13- valent pneumococcal  
94 conjugate vaccine (PCV13) we aimed to determine the epidemiology and capsule  
95 composition of different 19A subtypes in different nutritional environments.

96 **MATERIAL AND METHODS**

97 **Bacterial strains and serotype 19A subtype analysis.** Serotype 19A subtype strains were  
98 selected from a Swiss national pneumococcal surveillance program (20). In order to detect  
99 the different described 19A subtypes (19) we analyzed 158 pneumococcal serotype 19A  
100 isolates derived from the upper respiratory tract of infant and adult outpatients with signs of  
101 upper respiratory tract infection (20). Antimicrobial susceptibility for penicillin,  
102 sulfamethoxazole / trimethoprim (SXT) and erythromycin was determined as previously  
103 described (20). In brief, minimum inhibitory concentration (MIC) for penicillin non-  
104 susceptibility was  $\geq 0.06$  mg/L while for erythromycin and SXT the disk diffusion method was  
105 performed (intermediate and resistant were considered as non-susceptible). A two-step PCR  
106 protocol was used to determine the 19A subtype of each strain using the following  
107 conditions. The first PCR was done with two primer pairs: rmlb\_1\_f -GAT GGT GAG AAG  
108 AAC AAT AAG; rmlb\_2\_f - GAC GGT GAG AAG AAC AAC AAG; rmlid\_1\_r- CTT CAT TAC  
109 GTT CAT CCA ATA and rmlid\_2\_r CAG CTG AAG ACA CCA CTT GGT. PCR conditions  
110 were initial heat activation 6 min 95°C, 30 cycles of 30s 95°C, 20s of 60°C and 90s of 72°C  
111 with a final extension of 5 min 72°C. The reaction mixture contained 2.5  $\mu$ L of FastStart *Taq*  
112 reaction buffer without  $MgCl_2$ , 2.7  $\mu$ L of 25 mM  $MgCl_2$  stock solution, 4  $\mu$ L of 1.25 mM  
113 deoxynucleoside triphosphates (0.2 mM final), 0.2  $\mu$ L (1 U) of FastStart *Taq* polymerase (all  
114 from Roche Molecular Biochemicals, Rotkreuz, Switzerland), and 0.25  $\mu$ L of each primer  
115 (100  $\mu$ M stock resulting in 1  $\mu$ M final concentration, Microsynth AG, Balgach, Switzerland) in  
116 a total volume of 25  $\mu$ L. PCR products were visualized on 1% agarose gels. A resulting PCR  
117 product of 560 bp indicated subtypes 19A-I and 19A-II whereas a band of 425 bp indicated  
118 subtype 19A-III. For isolates within the first group (19A-I/19A-II), a second PCR reaction was  
119 performed to discriminate between the two groups using the following primers: wzg\_2\_f -  
120 AGT TGA TTC GTC CAT CCA CAC T; wzg\_3\_f -GGA ATT GAC ACA TAT GGT CCT and  
121 wzh\_r -GCC AAG AGA GCC TTG CTT TCC. The resulting PCR products were 654 bp and  
122 833 bp for types 19A-I and 19A-II, respectively.

123 Strains were further characterized with *plyNCR*-RFLP as previously described (21, 22). We  
124 selected the following strains for further analysis of the capsule composition (Table 1):  
125 109.44 and 501.14 (subtype 19A-I), 501.24 (subtype 19A-II), and 412.49 (subtype 19A-III).  
126 For all selected subtype test strains, multi locus sequence typing (MLST) was determined as  
127 previously described (22). In addition, we included the internationally spread Hungary-19A-6  
128 strain (23), which was classified as a 19A III. Serotype 19F strains 505.32 and B201.73 were  
129 selected for comparison as the polysaccharide repeat unit contains the same backbone  
130 monosaccharides but different glycosidic linkages between the repeat units. Both strains are  
131 clinical isolates derived from Swiss national surveillance programs (20, 24). In addition a  
132 capsule knockout mutant of strains B201.73 was generated as previously described (25, 26)  
133 to assess the amount of background signal in capsule extracts. Commercially available  
134 capsule polysaccharide of serotype 19A from the American Type Culture Collection (ATCC,  
135 Molsheim Cedex, France) was used as a reference standard.

136 Chi-Square and Fisher exact tests were used to calculate p values for epidemiological  
137 analyses. A value of  $p \leq 0.05$  was considered significant. In addition, we used a multivariate  
138 logistic regression model to ascertain the strength of the association between PCV7 era and  
139 19A subtypes, and adjusted for potential confounders like age (0-1 (base), 2-4, 5-15 and >15  
140 years), sex (male gender as base), penicillin resistance (susceptible chosen as base),  
141 erythromycin resistance (susceptible chosen as base), SXT resistance (susceptible chosen  
142 as base) and geographical origin (east Switzerland as base). Adjusted odds ratios (aOR)  
143 with 95% confidence intervals (95%CI) were received (table S1). Trends over time in the  
144 prevalence of different 19A subtypes before the introduction of PCV7 were analyzed using  
145 linear regression.

146 **Growth conditions, polysaccharide purification, hydrolysis and high performance**  
147 **liquid chromatography (HPLC).** Strains were handled and grown as described previously  
148 (25). The undefined growth medium pneumococcal inoculation medium (PIM) which has  
149 been reported to alter 19A capsule composition (6), as well as a chemically defined medium

(CDM) by van den Rijn and Kessler (27) were used. CDM was supplemented with 5 mg/L choline chloride (28), but made without monosaccharides to allow modification of the type and concentration of the carbon source for each experiment. Monosaccharides were added to the CDM and the mixture was sterile filtrated using a 0.22  $\mu$ m filter unit (TPP, Trasadingen, Switzerland). Two forms of CDM were created, one supplemented with 55 mM Glucose and the other one mimicking the composition of the salivary mucin MG1, i.e.: N-acetylneuraminic acid (NeuNAc):fucose (Fuc):galactose (Gal):N-acetylglucosamine (GlcNAc):N-acetylgalactosamine (GalNAc) = 1:5:4:3:1 (29)). For one experiment pooled human saliva from ten healthy volunteers was collected using Salivette (Sarstedt, Nümbrecht, Germany). After centrifugation with 1500 x g for 2 minutes samples were pooled and sterile filtrated with 0.22 $\mu$ m centrifugal filter units (Millipore, Billerica, MA) at 5000 x G for 20 minutes as previously described (30).

Capsules of strains grown in different growth media were released by overnight incubation in 1% phenol, separated from the bacteria by centrifugation and filtration, and then purified with sodium acetate/ethanol precipitation, followed by protease and nuclease digestion of remaining contaminants, and finally cut-off filtrated as described (25). The extracted polysaccharides were then completely hydrolyzed by trifluoroacetic acid (TFA) (31). The monosaccharide composition of capsular polysaccharides of strains grown in CDM was determined by high performance liquid chromatography (HPLC) analysis of fluorescently labelled monosaccharides as previously described (25, 32-35), whereas the PIM extracts were analyzed on a system consisting of an ASI-100 autosampler and P680 HPLC pump (DIONEX, Sunnyvale, CA, USA) with an injection volume of 20  $\mu$ L per sample. Separation of the monosaccharide was done with a flow rate of 0.85 mL/min as follows: 6% solvent B isocratic for 35 minutes followed by a linear gradient from 6 to 12% solvent B over 20 minutes. Then, the column was washed with 100% solvent B for 10 minutes and 100% solvent A for 15 minutes followed before re-equilibrating the system with 6% solvent B for 10 minutes. Total run time was 90 minutes and data was collected for 55 minutes using an L-7480 Fluorescence Detector (Merck Hitachi, Darmstadt, Germany). A Luna 5 mm, C18

178 column (Phenomenex, Torrance, CA) was used for separation and column temperature was  
179 maintained at 24 °C using a TCC-100 column oven (Thermo Scientific Dionex, Reinach,  
180 Switzerland). Peaks were identified by comparing retention time with monosaccharide  
181 standards analyzed in the same run (Figure S1A). As N-acetylated aminosugars are  
182 deacetylated during hydrolysis with TFA (36), deacetylated aminosugars were used as  
183 standards for their acetylated counterpart (e.g., mannosamine for N-acetyl-mannosamine).  
184 Negative controls included in each experiment were medium negative control for growth,  
185 extraction, hydrolysis and HPLC. HPLC raw data was exported into GraphPad Prism  
186 (Version 5, GraphPad Software, Inc.) for creating figures.

187 **Gas chromatography – mass spectrometry (GC-MS).** GC-MS analysis of alditol acetates  
188 of the polysaccharide hydrolysates from strains 109.44 grown in PIM and 501.24 grown in  
189 PIM, pooled saliva, and CDM glucose was performed as a control, as previously described  
190 (37, 38).

191 **Nuclear magnetic resonance spectroscopy (NMR).** NMR data were collected on a Bruker  
192 Avance II (500 MHz;  $^1\text{H}$ ) spectrometer equipped with a 1.7 mm triple-resonance ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  
193  $^{31}\text{P}$ ) microprobe head. The samples were extracted as described above and prepared as  
194 follows: The full amount of each capsule extract (~4 – 5 mg) was dissolved in 50  $\mu\text{l}$  of  $\text{D}_2\text{O}$   
195 and 40  $\mu\text{l}$  of the resulting mixtures were transferred into 1.7 mm NMR tubes. The water  
196 resonance was suppressed using a classical presaturation scheme. HSQC spectra were  
197 collected on a Bruker Avance III HD (600 MHz) spectrometer equipped with an inverse 5mm  
198 TCI helium cryoprobe. All spectra were acquired at a regulated temperature of 298 K and  
199 calibrated to the residual water peak (4.766 ppm). For the interpretation of the received  
200 carbon and hydrogen shifts, results from previous studies were used as guidance for the  
201 capsule structure determination of the 19A capsule extracts (4, 39, 40).

202

203

204 **RESULTS**

205 **Epidemiology of non-invasive 19A subtypes.** We first aimed at analyzing the distribution  
206 of the different pneumococcal serotype 19A subtypes within the Swiss Sentinel Network  
207 collection of upper respiratory tract isolates. PCV7 had been recommended in Switzerland  
208 since late 2005 to all children under the age of 24 months in a three dose schedule given at  
209 2, 4 and 12 months and since August 2006 the vaccine has been fully reimbursed by the  
210 mandatory Swiss health insurance. Serotype 19A strains isolated from the upper respiratory  
211 tract between 1998 and 2011 were analyzed. In total, 158 19A isolates were screened for  
212 the three described subtypes using a two-step PCR protocol described above. Between  
213 1998 and 2005, we identified 30 (57.7%), 5 (9.6%) and 17 (32.7%) isolates belonging to  
214 subgroups 19A-I, 19A-II, and 19A-III, respectively. After 2006 until 2011, a significant relative  
215 difference was noted overall ( $p=0.02$ ) but also individually for the subgroups 19A-I ( $p=0.02$ )  
216 and 19A-II ( $p=0.02$ ) as 40 (37.7%), 28 (26.4%) and 38 (35.8%) isolates were detected with  
217 the 19A-I, 19A-II, and 19A-III subtypes, respectively (Figure 1A). There was still a significant  
218 shift even after data from the PCV7 introduction year (2006) were excluded ( $p=0.03$ ). We  
219 found no evidence for a difference of 19A subtypes distribution according to age (Pre versus  
220 post introduction of PC7 eras over age groups of  $\leq 1$ , 2-4, 5-15 and  $>15$  years; Fisher's exact  
221 test;  $p=0.3$ ). In addition, there was no indication of a time trend for the frequency of 19A  
222 subtypes before the PCV7 was present (Data not shown). As for molecular types derived by  
223 *plyNCR*-RFLP typing, *plyNCR*-RLPF types 1 (55.7%) and 16 (18.4%) were the most  
224 frequent within the 158 strains but we did not detect a significant shift of molecular types  
225 between pre and post PCV7 introduction era (Figure 1B). In addition we revealed that  
226 antibiotic resistances within the 19A strains were generally high and that 19A II is  
227 significantly more susceptible towards penicillin, erythromycin, and SXT as compared to the  
228 other subtypes (Figure 1C). However, calculating a multivariate logistic regression model we  
229 confirmed that there was strong evidence that, compared to 19A I, the odds of observing  
230 subtype 19A II after introduction of PCV7 was 6 times higher than before PCV7, and that this

231 association was independent of antimicrobial resistance, geographical region, age or sex  
232 ( $p = 0.005$ ; **Table S1**).

233 We then selected at least one strain of each subtype for further laboratory analysis to  
234 determine capsular composition of the different subtypes (Table 1). Selected subtype strains  
235 represented different genetic backgrounds as indicated by MLST and *plyNCR*-RFLP  
236 analysis (Table 1).

237 **Method validation.** To assess the degree of contamination of capsule extracts with cell wall  
238 and other components, we first compared the monosaccharide composition of hydrolyzed  
239 capsule extracts of a serotype 19F clinical isolate B201.73 with extracts of its isogenic  
240 capsule knockout mutant (B201.73 $\Delta$ cps) by HPLC with fluorescence detection (Figure S1B).  
241 No rhamnose peaks were detected for the strain without a capsule, but small amounts of  
242 glucose and higher amounts of amino sugars including mannosamine could be detected,  
243 most likely deriving from cell wall polysaccharide (CWPS) and from murein layer.  
244 Furthermore, hydrolysis with TFA is known to produce varying amounts of hydrolysis-derived  
245 (di)saccharides (Figure S1B). This contamination was usually present in capsule extracts  
246 from tested strains and was higher in amount as compared to the commercially available  
247 purified pneumococcal polysaccharide (Figure 2). Furthermore, after complete hydrolysis a  
248 linkage analysis is not possible and only monosaccharide determination can be done (e.g.,  
249 same chromatogram for serotype 19A and 19F). Therefore, we used the HPLC method only  
250 as a screening tool for additional neutral monosaccharides under different growth conditions  
251 (i.e. galactose and fucose).

252 **Capsule composition analysis of 19A subtypes by HPLC and GC-MS.** We then analyzed  
253 the capsule composition of a strain for each subgroup (109.44 and 501.14 (subtype 19A-I),  
254 501.24 (subtype 19A-II), and Hungary-19A-6 and 412.49 (subtype 19A-III) grown in CDM  
255 supplemented with 55 mM glucose. We did not detect additional neutral monosaccharides  
256 and comparison of the used isolates revealed no differences among the strains indicating

the same monosaccharide backbone built of glucose, rhamnose and (N-acetyl)-mannosamine. As expected, HPLC chromatograms were not able to differentiate 19A from 19F as both serotypes contain the same monosaccharide compositions (Figure 2A). We then analyzed the capsular extracts from the ATCC standard (Figure 2B) and from 19A subtypes grown in the undefined medium PIM (Figure 2C). Again, no additional neutral monosaccharides were detected and thus reported additional monosaccharides (galactose and fucose would have been expected on the neutral side based on the literature (6)) were not seen in our preparations. As HPLC allows only the identification of peaks based on their retention time in comparison to standards, the presence of the neutral monosaccharides in capsule extracts was confirmed for 109.44 (19A-I) grown in CDM with 55 mM Glucose (Figure S3A) and PIM (Figure S3B) and 501.24 (19A-II) grown in PIM (Figure S3C) with GC-MS (which revealed glucose and rhamnose in all preparations). GC-MS also confirmed a lower degree of contamination with cell wall and other compounds in the ATCC standard compared to subtype capsule extracts (Figure S3D).

To mimic saccharide nutrients present in the natural human environment of *S. pneumoniae*, 109.44 (19A-I) was grown in CDM with monosaccharides contained in human mucin (5.5 mM total concentration of the mucin building monosaccharides in ratios as determined for the salivary mucin MG1) and 501.24 (19A-II) was also grown in pooled human saliva collected from 10 healthy volunteers after sterile filtration. No additional neutral monosaccharides were identified to be present in the polysaccharide capsule extracted from the strains grown under these conditions compared to capsule extracted from strains grown in CDM supplemented with glucose or PIM but the signal to noise ratio was much lower in saliva grown capsule (Figure S2 and S3E).

#### **NMR analyses reveal no structural difference between subtypes.**

In order to confirm the proposed structures of the oligosaccharides we compared the anomeric region (4.8-6.0 ppm) in the <sup>1</sup>H-NMR of all strains grown in CDM supplemented with 55mM glucose (Figure 3A). We were able to clearly differentiate the capsule of serotype 19A

284 strains from 19F capsule. Comparison of carbon and hydrogen shifts with previously  
285 reported NMR spectra confirmed the following structures for serotype 19F:  $\rightarrow 2$ )- $\alpha$ -L-Rha-  
286 (1 $\rightarrow$ PO4 $\rightarrow$ 4)- $\beta$ -D-ManNAc-(1 $\rightarrow$ 4)- $\alpha$ -D-Glc-(1 $\rightarrow$  and for serotype 19A:  $\rightarrow 3$ )- $\alpha$ -L-Rha-  
287 (1 $\rightarrow$ PO4 $\rightarrow$ 4)- $\beta$ -D-ManNAc-(1 $\rightarrow$ 4)- $\alpha$ -D-Glc-(1 $\rightarrow$  . In addition, no differences among the  
288 serotypes 19A subtypes were detected. We then performed an identical  $^1\text{H}$ -NMR analysis of  
289 all strains grown in PIM which has been reported to alter the composition of 19A capsule (6).  
290 The spectra were again consistent within 19A subtypes but different from serotype 19F  
291 capsular polysaccharide (Figure 3A). Based on those results, it can be stated that the  
292 capsule composition is independent of tested growth medium as the patterns were identical  
293 to each other and to the ATCC reference 19A polysaccharide. Only a slight shift was  
294 observed for the capsule analysis of the Hungary 19A-6 strain. However, the overlay of the  
295 2D  $^1\text{H}$ - $^{13}\text{C}$  HSQC-NMR spectra of this isolate grown in PIM and CDM supplemented with  
296 glucose revealed identical patterns for the H-atoms of the anomeric region as illustrated for  
297 rhamnose, N-acetyl mannosamine and glucose (Figure 3B). The full 2D Spectrum is shown  
298 in Figure S4.  
299

300 **DISCUSSION**

301 In this study we demonstrated that the distribution of pneumococcal serotype 19A subtypes  
302 changed after the implementation of PCV7 in Switzerland. However, all analyzed capsular  
303 extracts from serotype 19A subtypes grown in defined medium CDM and the undefined  
304 medium PIM showed a capsule composition which was consistent with the one proposed  
305 based on genetic analysis. Furthermore, we did not find any evidence for additional side  
306 chains altered repeat units or linkage changes under different nutritional conditions. .

307 During the time of widespread use of PCV7 in Switzerland the serotype 19A subtype  
308 distribution changed substantially compared to the pre-vaccine period. Similar shifts with  
309 decreasing 19A-I and increasing 19A-II subtypes after the introduction of PCV7 have also  
310 been reported in the Netherlands (19). Furthermore, although classified as group III by PCR,  
311 based on its genome sequence the Hungary 19A-6 strain contains an additional insertion  
312 element downstream of the last *cps* gene (*rmID*) and differs from the subgroup III strains as  
313 defined by Elberse et al. (19) which could suggest an additional serotype 19A subgroup.

314 Given the identical capsule structure for all tested 19A subtypes as revealed for the first time  
315 in our study using NMR, HPLC and GC-MS, no alteration of vaccine effectiveness due to  
316 capsular differences between individual subtypes is suggested. Furthermore, the lack of anti-  
317 19F antibody cross-protection against serotype 19A can therefore not be explained by  
318 selection of 19A subtypes with altered capsule structures which supports recent discoveries  
319 suggesting a general low protection due to conformational difference in polysaccharide  
320 structures of 19F and 19A (17, 18).

321

322 However, other factors could explain the observed subtype shift after the introduction of  
323 PCV7 in Switzerland. For example, changes in 19A subtypes could be due to changes in  
324 clonal distribution although we did not detect a significant shift of molecular types as  
325 determined by *plyNCR*-RFLP. However, additional typing methods or whole genome

sequencing might be more appropriate to investigate this hypothesis. As for antibiotic resistance being a potential driver for the subtype shifts, we revealed that 19A II is significantly more susceptible to antibiotics as compared to the other subtypes indeed, but as 19A II increases in the PCV7 era, increasing antibiotic resistance can therefore not explain the changes in the distribution, though antibiotic resistance within serotype 19A strains is generally high as previously shown (41). A subtype redistribution under increasing vaccine selection pressure after the introduction of PCV13 would be unexpected, although it has been speculated that there might be a difference in capsule thickness for different subtypes which might lead to differences in opsonophagocytotic susceptibility (19).

Previously reported experiments showing additional side chains in 19A isolates grown in PIM could not be replicated (6). An explanation for this finding might be a strain-specific genetic alteration in previous studies. Indeed, it has been recently reported that serotype 11D has two different capsular polysaccharide repeating units in a ratio of 1:3 (25% and 75%, respectively) due to a bispecific transferase WcrL (42). Although precursors of capsular galactose and N-acetyl-glucosamine might be available due to their synthesis in other pathways (43), the (environment-dependent) addition of 2 side chains comprised of three additional monosaccharides is expected to be reflected with at least additional glycosyltransferase enzymes within the capsule locus involved in their linkage, and a switch of the glycosidic linkage between rhamnose and glucose would suggest mutations resulting in bispecificity or two copies of the wzy polymerase (3). To our knowledge, neither of these two possibilities have been detected in 19A strains (3). However, variation of the repeat unit structure would be suspected to have an influence on the antigenicity thus resulting in suspect serotyping results (i.e., less reactive with anti-19A antiserum) which were not observed in this study. However, given the increasing vaccine selection pressure after the introduction of PCV13, we recommend capsule structure determination of emerging clones and/or serotypes given recent discoveries of novel serotypes and capsule variants (42, 44-47). The importance of chemical capsule structure analysis is also highlighted by a recent

353 analysis of serotype “6E” capsule, demonstrating that this potential new serotype determined  
354 at the genetic level produces capsular polysaccharide identical to 6B capsular  
355 polysaccharide (48).

356 A particular strength of this study is the use of multiple techniques for capsule structure  
357 determination, which enhances the reliability of reported findings. We first used an HPLC  
358 based approach to determine if additional neutral sugars were incorporated into the capsule  
359 and validated the methodology with GC-MS. As this technique requires complete hydrolysis  
360 a linkage analysis was not possible in this first step. Furthermore, although this method has  
361 been demonstrated to have high normalized recoveries of neutral monosaccharides  
362 rhamnose and glucose of serotype 19F monosaccharides (32), TFA hydrolysis has also  
363 been reported to be less satisfactory for polysaccharides with aminosugar moieties (32) and  
364 it has been reported that disaccharides can be formed during hydrolysis based on different  
365 stability of intramolecular bonds (32) which also occurred in our experiments.

366 Results showed traces of contamination of cell-wall components in our preparations, which  
367 is a common co-extracted compound in pneumococcal capsule preparations probably  
368 because the capsule is covalently linked to the cell wall (32, 49, 50). To determine linkage  
369 analysis and further characterization of the capsule oligosaccharide repeat units, we  
370 performed additional 1D and 2D NMR analysis of polysaccharides from unhydrolyzed  
371 capsule extracts. The major limitation of this study is that the number of different 19A  
372 subtype strains analyzed was rather small. However, we chose at least one sample of each  
373 of the currently known subtypes and it can therefore be expected that our study is  
374 representative. Although we did not find evidence for nutrition-dependent variations of  
375 capsule structures, this cannot be considered as final proof for an absence of such  
376 variations. Furthermore, we did not have the same strains or capsule extracts for which a  
377 nutrient-dependent variation has been reported as a reference for the assays used (6).

378 In summary, the polysaccharide capsule composition for tested serotype 19A subtypes was  
379 consistently composed of the same trisaccharide repeat unit. Although we therefore do not

380 expect a structural advantage for certain subtypes it remains to be determined how the 19A  
381 subtype distribution will be affected by PCV13. We did not detect any nutritional  
382 environment-dependent alterations of the capsule composition. However, given the genetic  
383 plasticity of *S. pneumoniae* and current vaccine selection pressure, we propose to test the  
384 capsule composition of emerging serotype 19A clones, especially in cases where there is no  
385 other explanation for a selective advantage such as antibiotic resistance or loss or  
386 acquisition of other virulence factors.

387 **ACKNOWLEDGMENTS**

388 We would like to thank Professors Adrian F. Brugger, Peter Bütikofer, Johannis P.  
389 Kamerling, Vincent Perreten and Jean-Louis Reymond for advice and help with chemical  
390 questions and Suzanne Aebi for excellent technical assistance. We are grateful to Dr.  
391 Lindsey Bomar for critical comments and helpful discussions. We also thank Dr. Sandra  
392 Loss and Dr. Aitor Moreno from Bruker AG, Fällanden, Switzerland for their valuable support  
393 and providing access to their NMR facility and the Department of Anesthesiology, University  
394 Hospital Bern, Inselspital for providing the HPLC instrument. We also acknowledge the  
395 physicians who participate in the Sentinella surveillance system and who provided non-  
396 invasive sample material. The prospective surveillance study on colonising pneumococci  
397 within Sentinella has been funded by the FOPH (Federal Office of Public Health).

569 **FIGURE LEGENDS**

570 **FIGURE 1. A. Epidemiology of 19A subtypes (19A-I, 19A-II, and 19A-III) 1998-2011.** A  
571 total of 158 serotype 19A strains isolated within the Swiss Sentinel Network (outpatients with  
572 upper respiratory tract infections) were analyzed. 1998-2005 was considered as pre-  
573 conjugate vaccine (PCV7) era. The % of tested isolates and subgroup assignment for both  
574 periods is shown. There was an overall significance as derived by Fisher exact test  
575 ( $P=0.02$ ). Chi-Square test revealed significant changes in relative frequency between the  
576 two periods for subtypes 19A-I ( $p=0.02$ ) and 19A-II ( $p=0.02$ ). 95% confidence intervals (CI)  
577 are indicated. **B. Distribution of molecular types as determined by *plyNCR*-RFLP 1998-**  
578 **2011.** Shown are the most frequent *plyNCR*-RFLP types (Types 1 and 16). The remaining  
579 types were pooled within 'others'. There was no overall significance as derived by Fisher  
580 exact test for the two different eras. 95% confidence intervals (CI) are indicated. **C.**  
581 **Antibiotic resistance of serotype 19A isolates against penicillin, erythromycin, and**  
582 **sulfamethoxazole / trimethoprim (SXT), 1998-2011.** Minimum inhibitory concentration  
583 (MIC) for penicillin non-susceptibility was  $\geq 0.06$  mg/L while for erythromycin and SXT the  
584 disk diffusion method was performed (intermediate and resistant were considered as non-  
585 susceptible. 19A II is significantly more susceptible towards penicillin (Fisher exact test;  $p<$   
586  $0.001$ ), erythromycin ( $p=0.014$ ), and SXT ( $p<0.001$ ) as compared to the other subtypes.  
587 95% confidence intervals (CI) are indicated.

588 **FIGURE 2. HPLC chromatograms of serotype 19A subtypes and 19F strain B201.73**  
589 **grown in CDM and PIM.** HPLC composition analysis of hydrolyzed polysaccharide capsule  
590 of clinical isolates of serotype 19A subtypes grown in chemically defined medium with 55  
591 mM glucose (A) compared to ATCC purified pneumococcal serotype 19A polysaccharide  
592 (B), and the pneumococcal inoculation medium PIM (C). Y-axis shows fluorescence (FU)  
593 and chromatograms were stacked to facilitate comparison. Peaks of mannosamine (Man-N),  
594 rhamnose (Rha) and glucose (Glc) are labeled.

595 **FIGURE 3. A. 1D NMR spectra of serotype 19A subtypes.** Shown are  $^1\text{H}$  NMR spectra of  
596 capsular polysaccharide purified from each subtype grown in CDM 55 mM glucose (black)  
597 and PIM (red) compared to serotype 19F and ATCC 19A purified pneumococcal  
598 polysaccharide. **B. 2D NMR.** Shown is a superimposition of  $^1\text{H}$ - $^{13}\text{C}$  HSQC-NMR spectra of  
599 the anomeric region from PS from Hungary 19A-6 capsule grown in CDM and PIM.
